An article, note, or other material appearing in the *American Journal of Agricultural Economics* may not be republished in full or in part without the express written permission of the editor.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except that concerning "Books Reviewed" and "Books Received," should be addressed to the editor, William G. Tomek, Department of Agricultural Economics, Cornell University, Ithaca, New York 14853.

Communications concerning books for review and books submitted for announcement in the *Journal* should be sent to the book review editor, Francis E. Walker, Department of Agricultural Economics and Rural Sociology, Ohio State University, Columbus, Ohio 43210.

Economic Performance and Energy Intensiveness on Organic and Conventional Farms in the Corn Belt: A Preliminary Comparison

Robert Klepper, William Lockeretz, Barry Commoner, Michael Gertler, Sarah Fast, Daniel O'Leary, and Roger Blobaum

Recent energy and environmental problems in U.S. agriculture have stimulated interest in alternative technologies or systems of agricultural production. Large-scale, mechanized organic farms that use little or no inorganic fertilizers or chemical pesticides may be one such alternative. The crop production on fourteen matched pairs of organic and conventional Corn Belt farms was studied to determine the relative value of crop output, net returns, energy intensiveness, and labor requirements. The results of this preliminary study suggest that organic farming warrants more intensive research.

Key words: Corn Belt, crop production technology, energy intensiveness, organic farming.

Circumstances of the past few years have generated concern, at least in some circles, over the heavy reliance of modern agriculture on inorganic fertilizers and chemical pesticides. This concern centers on energy and environmental questions. The events of 1973 and 1974 suggest that farm income and food production are vulnerable to energy price fluctuations and shortages under circumstances previously dismissed as highly unlikely.[1] On the environmental side, in the last few years five agricultural pesticides have been removed from the market by the Environmental Protection Agency or limited to use under proscribed circumstances to forestall potential environmental damage. There is also continuing concern over the movement of fertilizer nutrients to ground and surface waters with possible eutrophication and public health consequences.

These problems have given rise to a growing interest in technologies or systems of agriculture that are less energy intensive and less vulnerable to energy price fluctuations and shortages and that have smaller adverse environmental impact. The proportion of total energy consumption accounted for by farm output is small—about 2.5% in the United States (Federal Energy Administration). Large energy savings could not be accomplished by adopting less energy-intensive technologies, but individual farmers could be made less vulnerable to fluctuations in energy prices and supply. At the same time the uncertain world food situation requires

Editor's note: This article was invited by the editor to stimulate thought, discussion, and research on the economics of organic farming.

Robert Klepper and William Lockeretz are research associates, Barry Commoner is director, and Michael Gertler, Sarah Fast, and Daniel O'Leary are research assistants at the Center for the Biology of Natural Systems, Washington University, and Roger Blobaum is an agricultural consultant in Creston, Iowa.

This research was supported by the Research Applied to National Needs Program of the National Science Foundation, Grant No. AER-74-18438. Any opinions, findings, conclusions, and recommendations expressed in this publication are those of the authors and do not necessarily reflect the views of the National Science Foundation. The authors benefited from the comments and suggestions of an overview committee on an earlier report on which this paper is based as well as comments from anonymous reviewers. Any remaining errors or deficiencies are the authors' responsibility. The cooperation of the personnel of the Agricultural Stabilization and Conservation Service and the Soil Conservation Service in helping locate conventional farmers is gratefully acknowledged.

[1] These unforeseen events, attributable in part to the energy crisis, include a shortage of propane for drying grain in the fall of 1973, shortages of fertilizer in the spring of 1974, and substantial increases in the prices of many agricultural inputs including increases in the prices of fertilizers relative to crop prices.

that these alternative technologies be highly productive so that world food supplies are not diminished.

One alternative agricultural system that does not rely on chemical fertilizers or pesticides is "organic farming," also known as "natural farming" or "biological farming." In this system plant nutrients are supplied through organic wastes (particularly livestock manures), leguminous green manures, purchased organic materials, and inorganic minerals such as rock phosphate that have not been chemically treated. Crop rotations also serve to reduce weed and insect problems. In some instances biological control methods are used in which beneficial insects or neutered insects are introduced into fields.

Although the term organic farming is frequently associated with small-scale, labor-intensive, subsistence farms, there are organic farmers who use essentially the same mechanized methods of crop production as their conventional counterparts but who use little or no inorganic fertilizers or chemical pesticides. We have studied the economic performance and energy consumption in the 1974 and 1975 crop years of fourteen commercial-size organic farms in the Corn Belt. Their farming methods lie near one end of a continuum of agricultural techniques of varying reliance on chemical inputs.

The purpose of the study was to determine whether organic farming warrants more intensive research. We started from the widely held premise that there is an overwhelming advantage in conventional over organic farming. The methods of analysis were matched to the problem, that is, the methods were intended to detect large differences in the performance of the two systems. If this preliminary study shows little or no difference in the two systems, further and more intensive research using more refined methods is called for. Specifically, we sought to answer the following questions in a preliminary way: Is organic farming competitive with conventional methods of crop production at the relative prices of the past few years? Is it less energy intensive? What reduction in agricultural output, if any, would result if the system was adopted to a greater degree?

The organic farming methods examined could not be adopted by all Corn Belt farmers at current prices if for no other reason than the sum of all organic wastes from farm and municipal sources falls short of the quantity necessary to meet the nutrient requirements of the present crop mix. However, the availability of livestock manures on many farms in the Corn Belt makes organic techniques or technologies that lie between organic and conventional practice an alternative for a significant portion of Corn Belt farms.[2]

In this paper the performance of fourteen organic farms is compared with the performance of an equal number of conventional farms, each of which was matched to one of the organic farms in the study. All of the organic farms raise both field crops and livestock, and each relies on livestock manure as a source of plant nutrients. As one of the criteria for matching, which are explained more fully below, the conventional farms also must have both field crops and livestock.[3] However, their performance is compared for crop production only because it is mainly in crop production that the technologies diverge. This clearly is a limitation of the study. More extensive research into organic farming should consider the farm enterprise as a whole.

Methods

No census or other comprehensive listing of organic farms exists in the Corn Belt. Consequently, it was not possible to select a random sample that represents the organic farm population. An ad hoc procedure was used to locate organic farms, primarily word of mouth. On the basis of information on location, size, length of time the farm had been operated using organic methods, a preliminary judgment of each organic farmer's competence as a farm manager, and the resources available, we chose a sample of fourteen organic farms. The organic farms chosen in this manner are a series of case studies (a judgment sample). Of course, the inability to

[2] In all the Corn Belt states, with the exception of Illinois, more than half of all the farms surveyed in the 1969 *Census of Agriculture* had as their principal source of income the raising of livestock or the production of dairy products.

[3] We deliberately chose matched conventional farms that have livestock rather than cash grain farms. The supply of manure on these farms and their need for roughages in cattle-feeding programs makes the adoption of organic methods easier on purely technical grounds than would be the case for a cash grain farm. At the same time, their relatively heavy reliance on inorganic fertilizers and pesticides clearly differentiates their technology from that of the organic farms in this study.

statistically sample limits the extent to which inferences from the results can be made to a larger population of Corn Belt farms. Under the circumstances, this was unavoidable.

The organic farms are operated as family enterprises by full-time farmers. The total acreage of each farm lies within a range of 175 to 800 acres. They are widely distributed over the central and western portions of the Corn Belt. Four are located in Iowa, four in Illinois, and two each in southern Minnesota, northern Missouri, and eastern Nebraska. Each had been farmed organically for four or more years prior to 1974. All the farms have one or more of the following forms of livestock: beef cow herd, cattle on feed, hogs, dairy cattle, or sheep.

On the organically farmed land in the study, none of the farmers used inorganic nitrogen fertilizer or urea, acidulated phosphates (e.g., triple superphosphate), or, with one exception, conventional potassium fertilizer (muriate of potash). Some used commercial organic fertilizers, phosphate rock, or powdered rock containing trace minerals.[4] No insecticides are used on any of these farms, and in all but one case no herbicides are used. In all cases but one, the farms had previously been operated using at least some inorganic fertilizers and pesticides, generally with an intensiveness comparable to the majority of similar farms in the area.[5] The average length of time over which the farms were managed organically was six years prior to the start of the study.

A nearby conventional farm was selected as a match for each organic farm. This farm was required to raise both crops and livestock and to be as similar to the organic farm as the matching procedure allowed in soil type, size, and livestock inventories. Conventional farms that met or came close to meeting these criteria were located with the assistance of the staff members of county offices of the Agricultural Stabilization and Conservation Service (ASCS), who in most cases consulted with the local Soil Conservation Service (SCS) office before making recommendations. In addition we asked that all recommended farmers be "top management" operators as judged by local ASCS personnel. We did not have a measure of the managerial ability of the organic sample, but we had no reason to believe they are superior managers when taken as a group. The management criterion was applied to the conventional group to avoid biasing the results toward the organic farmers. Since the management criterion was applied together with other criteria on size, soils, and mix of operations, the extent to which the management criterion was met is not clear. Indirect evidence is presented below in the form of data on yields and fertilizer use by the conventional farmers in the sample. The lack of detailed soil maps in most of the counties in which the sample farms lie, the highly qualitative requirement for managerial ability, and the multiple criteria on which the matching took place made the matching procedure largely qualitative. The limitations of the matching procedure leave considerable room for within-pair differences in organic and conventional farms. Some indications of the success of the matching are given below.

Data were collected for each farm for the 1974 and 1975 crop years. Data for the 1974 crop year were collected in personal interviews of both groups of farmers in late winter and early spring of 1975. The data for the 1975 crop year were collected by means of questionnaires mailed to the farmers and returned by mail. For both crop years the following data were collected for each field: (*a*) crop(s) and yield(s); (*b*) application rates and costs of all fertilizers, pesticides, lime, and other materials; (*c*) application rates of manure; (*d*) tillage, planting, cultivation, and harvesting operations; and (*e*) seed variety, price, and seeding rate. Cropland for the crop year in question is all land that was ever in crops in the preceding five years; that is, it includes land in row crops and small grains, land in rotation pasture or hay in rotation with row crops or small grains, and land unharvested in that crop year. Land in permanent pasture or continuous hay is not cropland by this definition, nor, of course, is land in feedlots or woodlots or land associated with farm buildings.

Three measures were computed for com-

[4] There are many commercial organic fertilizers on the market. Most of these are proprietary products for which little or no information is available on the process by which they are produced or on their content aside from the required statement on nitrogen, phosphorus, and potassium content. We have not verified their authenticity as organic products, nor have we attempted to determine their content.

[5] Four of the organic farmers in this study rent additional cropland and use inorganic fertilizers and chemical pesticides on it under the terms of a rental agreement. In addition, in 1975 three of the organic farmers used a chemical of one sort or another on small portions of their own land. These fields were excluded from the analyses.

paring the relative performance of the farms in the study: the value of crop output per acre of cropland, a net return to cropping activity measure that accounts for most variable costs (fixed costs are discussed below), and the energy intensiveness of crop production measured in British thermal units (BTU's) per dollar of crop output and BTU's per acre.

We relied on farmer's reported yields, verified where possible by elevator receipts and consistency with storage facilities filled and sales. Because a large proportion of crops are fed to livestock on many farms, reported yields frequently could not be corroborated. Therefore, the yield data are subject to inaccuracies and possible bias. Crops were valued at statewide season average prices received by farmers (USDA June 1975–Jan. 1976).[6] These values in turn were aggregated over all crops and divided by cropland acres to obtain the value of crop output per acre of cropland.[7] Although some organic farmers sell their crops in specialty markets as organic grain and receive a premium, they were not credited with the premium. Season average prices were used to value the crops of both groups of farmers regardless of whether the crops were sold or consumed by livestock on the farm.

The net returns per cropland acre measure is the value of crop output per acre of cropland minus most variable costs per acre. Fixed costs are assumed not to differ between the two groups. There is evidence that this assumption is reasonable. The largest fixed costs associated with crop production for Corn Belt farms of the kind in this study are the value of land for its use in crop production; depreciation on machinery, equipment, and storage facilities used in crop production; and property taxes and interest on debt. Data on the estimated cash rental value of the cropland in each group, which are presented in the next section, suggest that no substantial error is introduced by assuming that the cost of land is the same for the two groups, although there is considerable variation within pairs. If this is so, then there would be no large difference in the property taxes on land imposed on each group for a uniform tax rate and assessment procedure. The data collected showed that the organic and conventional groups differed little in the type and size of machinery and equipment they owned and used for field operations,[8] although the number of pieces of equipment varied with the size of the farming operation, as one would expect. This suggests that depreciation on machinery and equipment did not vary greatly between the two groups. The conventional farmers had more high moisture grain storage facilities, but these differences were too small to be the source of significant differences in fixed costs. The roughly equal values for land, machinery and equipment, and grain storage facilities between the two groups suggest that little difference in interest expenses would exist if both groups have access to capital markets on the same terms.

The variable costs included in this study are the reported or imputed values for seed; fertilizers; pesticides; soil amendments; crop drying; and the fuel, lubrication, labor, and repairs associated with all tillage, planting, cultivation, material application (including manure spreading), harvesting, and on-farm crop hauling operations in the crop year.[9] Those excluded are rent (all farmers were treated as if they owned all the land they farmed), crop insurance, and the share attributable to crop production of each of the following: sales and social security taxes, workman's compensation and disability insurance, bookkeeping and office supplies, electricity, telephone, vehicle licenses and all

[6] For 1975 we first developed an average of monthly prices through January 1976, from which were estimated the averages for the entire crop year using historical patterns of seasonal variation.

[7] Where two crops were obtained from a single field in a crop year, e.g., soybeans after winter wheat or hay after a small grain nurse crop, the value of both crops was included. Yields for rotation pasture and hay crops grazed by livestock were computed in animal units from farmer's reports of the number and kind of animals grazing and the duration of grazing; one animal unit month of grazing was valued at one-fourth the season average price for one ton of hay.

[8] For example, the median horse power of the largest tractor owned was 89 and 94, respectively, for the organic and conventional groups. All farmers in each group had a row crop planter of at least four rows. Twenty-one percent of the organic farmers and 18% of the conventional farmers had row crop planters of more than four rows. About one-third of each group owns a combine with a corn head of more than two rows. However, the two groups do vary with respect to their preference for moldboard or chisel plows. One hundred percent of the organic group versus 50% of the conventional group use a chisel plow. A moldboard plow is used by 86% of the conventional group and by only 29% of the organic group.

[9] In addition, prorated costs of lime and other soil amendments that were applied less frequently than annually were included, as were the prorated costs of establishing rotation pastures and hay stands for stands lasting more than one year. Costs for the establishment of green manure crops that were plowed down prior to planting in a crop year were also included.

expenses for vehicles used for general purposes, and subscriptions and memberships.

For the purposes of computing the costs of crop production, we assumed that there are no differences between farmers and between the two groups in certain aspects of raising crops. The price per unit of standard inputs such as pesticides, propane for drying, diesel fuel, and gasoline were assumed to be equal for all farmers in the study for a given crop year. Fertilizer prices were assumed equal for all farmers in a state. (These data were taken from the USDA's *Agricultural Prices*, April, July, August, and October issues, 1974–75.) Each farmer's reports of the quantity of particular fertilizers and pesticides applied were valued at the standard prices. Other inputs such as organic fertilizers purchased by organic farmers and hybrid seed were valued at the prices reported by the farmers in the study.

Because the characteristics of the machinery and equipment owned and used for field operations differed little between the two groups, for any given field operation the same tractor and implement were assumed to be used on all farms and labor requirements and cost per acre for that operation, including the imputed cost of labor, were assumed to be the same for all farmers in the study in a crop year.[10] All farmers were assumed to harvest a particular crop with the same equipment and to have the same cost schedule where costs per acre vary with yield. The sole exception is that the distinction between harvesting corn on the ear with a corn picker or as grain with a combine was preserved.[11] Again, allowance was made for differences between years in the prices used to build up the cost estimates. The costs of on-farm hauling of crops were also standardized with respect to the truck or equipment used and the distance hauled in taking a particular crop out of the field to on-farm storage or to the farm gate.

The energy calculations were made using coefficients previously derived for specific operations, such as chisel plowing or grain drying, and for agricultural chemicals that are manufactured by energy-consuming processes.[12] Details of the derivations of these coefficients can be found in Commoner et al.; what follows is a brief summary.

Fuel requirements for drying, tilling, planting, cultivating, and harvesting operations were obtained by combining many different estimates from a wide variety of experiment station and extension service publications and personal communications, taking account of differences in the conditions under which individual values were measured. As in the estimates of the cost of field operations described above, each individual operation was assumed done with the same tractor and equipment complement on each farm, and the same energy coefficient was applied in the calculations for each farm using a particular operation. No adjustment was made for differences in soil type or soil moisture at the time of the operation. Fuel requirements for harvesting operations and hauling do vary by crop and yield in this study. Fuel used for drying was assumed to be liquid petroleum gas on all farms. A constant value was used for the liquid petroleum gas required to reduce the moisture content of a bushel of grain by 1%. This value was applied to the farmers' reported yield and moisture content at harvest. To calculate the fuel and energy requirements for drying, 85% of the corn was assumed dried to a final moisture content of 15.5%. As in the cost of drying, farmers who harvested and stored ear corn were charged the energy requirements for shelling and drying.

The indirect consumption of energy by farmers through fertilizers was calculated from reported application rates and energy coefficients derived for both the extraction and benefication of minerals and the process energy used in production of nitrogen, phosphorus, and potassium fertilizers. Compendia of chemical engineering and mining process-

[10] While no difference in costs and labor requirements for a particular field operation is assumed between farmers in the study, the costs and labor requirements of all field operations for a crop do differ between farmers according to the combinations of field operations each farmer reported used. If a farmer made more trips over his fields in preparing the ground for seeding, in cultivating to control weeds, or in manure spreading, he would show higher costs and labor requirments for field operations in the calculations.

[11] All corn, whether harvested as ear corn or corn grain, was assumed to be shelled and dried to 15.5% moisture, the standard for No. 2 corn grain. The cost of drying was computed as the product of a standardized cost for a percentage point of moisture and the difference between the reported moisture at harvest and 15.5%.

[12] Energy coefficients were developed in a number of studies of energy use for particular crops or for agricultural production as a whole (Hirst, Pimentel et al., Steinhart and Steinhart). But we chose to develop our own coefficients in 1974 because the coefficients existing at that time were either dated or based on processes that were not always representative of conditions in this country.

es, standard references on specific fertilizer industries, reports on individual processes, and unpublished data from the Sulfur Institute were the sources of data from which these coefficients were derived. The energy required to transport the fertilizer from factory to farm is small relative to the energy required in processing and manufacture and was ignored. Estimates were also made of the energy requirements for mining and processing lime and gypsum. A standard energy coefficient per hundredweight was used for all commerical organic fertilizers. This was based on personal communications with several organic fertilizer producers and the assumption that other organic fertilizers have similarly small energy requirements.

The great variety of pesticides used precluded careful estimates of the energy coefficients for each. An estimate of the energy input per pound of DDT was used with application rates to determine energy consumption. Although DDT is no longer used in U.S. agriculture, it is representative of an important class (chlorinated hydrocarbons) of both insecticides and herbicides. Indirect energy consumption in the form of pesticides is small relative to that in fertilizers and fuel, so that errors arising from this simplifying assumption are likely to be small when compared with total energy use on a conventional farm.

Effectiveness of the Matching Procedure

Some indications of the success of the matching procedure follow. The mean total farm size of the fourteen organic farms was 429 acres (ranging from 175 to 844 acres) and 479 acres for the fourteen conventional farms (range 171 to 849 acres). Acreage in cropland differs more between the two groups; the mean was 250 acres for the organic farms (range 113 to 420) and 348 acres for the conventional farms (range 124 to 769).[13] The mean livestock inventory in animal units was 101 and 63, respectively, for the organic and conventional groups in the 1975 crop year, and machinery and equipment do not differ greatly between the two groups (see note 8).

In addition, we asked two and sometimes three persons who are knowledgeable about local agricultural conditions in each county where the sample farms lie and who know the sample farms in that county to estimate the cash rental value of the cropland in the sample farms. These persons were usually the head of the local ASCS office, the extension agent, a Federal Land Bank official, or the head of the local SCS office. For each pair of farms the estimates of both farms were provided by the same person, except in three cases where the farms in a pair were in neighboring counties. The average estimated cash rental value of cropland was \$68 for the organic group and \$66 for the conventional group. The interquartile range was \$51 to \$74 and \$53 to \$83 for the two groups, respectively.

There is no reason to believe that overall the matched conventional and organic farms systematically differ in the productivity of their cropland or the characteristics of their machinery and equipment complements. Furthermore, the conventional farms in the sample appear to be typical of conventional farms in general in that they differ little from average statewide fertilization rates for major crops, and they apply herbicides and insecticides at rates that appear to be within the range of typical practices in the Corn Belt. Average fertilization rates for corn, soybeans, and wheat for the conventional sample in 1974 are presented in table 1. A weighted average statewide fertilization rate for each crop is given in the same table. These data show the conventional farmers to be close to the statewide average for each crop. The fact that they all have livestock and may apply

Table 1. Average Fertilization Rates, Conventional Sample, and All Farms in Same States, 1974

Crop	Conventional Sample	All Farms[a]
Corn	101-53-71	108-61-63
Soybeans	8-38-40	13-44-66
Wheat	53-67-57	55-61-53

[a] All rates are pounds N, P_2O_5, and K_2O per acre receiving fertilizer. Weighted average of statewide average fertilization rates. The weighting factor for each state is the number of farms in the conventional sample in that state on which fertilizer is used on the particular crop.

[13] On average the organic group has a smaller proportion of farm land in crops. There are several reasons for this. First, some members of the organic group farm additional cropland with chemicals, as explained above in note 5, and this land is not part of their "farm" for the purposes of this study. Second, the organic farms have more permanent pasture; they also have more grazing livestock.

some manure to these crops should be taken into consideration in interpreting the table.

Results

Although the two groups of farmers raise the same major crops, they do so in different rotations, so that they differ in the proportion of their cropland in each crop in a given year. As seen from table 2, corn (grain and silage) is the leading crop on both groups of farms; however, because of the importance of hay and pasture in organic rotations, row crops (corn and soybeans) average only 52% of cropland in the organic sample compared to an average of 73% on the conventional farms. Small grains are more prevalent on the organic farms because these crops are generally raised as nurse crops for new stands of hay or pasture.

Table 3 shows the yields obtained by the two groups of farms in 1974 and 1975. Because this table is intended to indicate how the two groups compared in yields, it is restricted to farms in which both members of a particular pair raised a particular crop. The clearest difference between the two groups is in corn grain, for which the conventional group had higher yields. Differences in wheat (1975) and hay (1974 and 1975) may be less meaningful because there were so few farms growing these crops.

Table 3 shows that, in general, yields improved in 1975 and that the advantage of the conventional group over the organic group was stronger in 1975. These are understandable consequences of the different weather patterns. In 1974, virtually every farm in our study was adversely affected by weather. In 1975, a few of the farms were affected by drought, but conditions were good for a large portion of the sample. Consequently, yields were appreciably better. The better relative performance of the conventional farms under these conditions might reflect the greater response in yields to nutrient availability at the margin when weather conditions are favorable.

Table 2. Average Fraction of Cropland in Various Crops by Type of Farm, 1975 and 1974

	Organic		Conventional	
Crop	1975	1974	1975	1974
	---------- % ----------			
Corn grain	25	24	39	35
Corn silage	6	8	4	6
Soybeans	21	21	31	31
Wheat	9	6	7	7
Oats	11	12	6	5
Hay or pasture[a]	25	25	12	15

Total[c]	100	101	102	103

[a] Established stands only.
[b] Includes milo, rye, barley, buckwheat, and new meadow seedings other than with nurse crop. (New seedings with nurse crop included under particular small grain.)
[c] Total greater than 100% because of double cropping.

Table 3. Average Yields by Type of Farm, 1975 and 1974[a]

	Organic		Conventional		Number of Pairs Raising Crop	
Crop	1975	1974	1975	1974	1975	1974
Corn grain	74	74	94	76	14	11
Soybeans	35	32	38	29	12	11
Wheat	28	28	38	29	4	4
Oats	58	56	60	60	5	5
Hay[b]	4.5	5.0	3.9	3.4	4	6

[a] Only for farms in which both members of matched pair raised the crop. Yields are bushel per harvested acre, except hay in tons per acre.
[b] Established stands only, used only for hay. (Stands that were partially cut and partially grazed are excluded.)

The yields obtained by all farms in this study, regardless of whether the matched farm in a pair raised the crop, are shown in table 4. In this case, the average yields of the two samples should not be compared to each other, since they reflect different portions of our study area. Rather, each group's yields were compared with the average yields obtained by all farmers in the same counties as the farmers in the sample who raise the crop. The conventional group did about as well as the population in general in 1974 and considerably better in 1975. The organic farmers did better than farmers in general in soybeans in both years and poorer in wheat and corn in 1975. In other cases, they did about the same or better than farmers in general.

Table 5 shows the average and median value of all crops produced on each type of farm expressed as the value per acre of cropland. The higher value of production on the conventional farms reflects two factors: the somewhat higher yields, especially for corn,[14] and the higher proportion of cropland

[14] The value of crop output per acre is not particularly sensitive to the yields reported by farmers for any one crop. For

Table 4. Average Yields for Both Samples and for All Farms in Same Counties

Crop	Year	Organic Sample	All Farms[a]	Conventional Sample	All Farms
Corn	1975	74 (n = 14)	90[b]	94 (n = 14)	88[b]
	1974	74 (n = 11)	75	71 (n = 14)	73

[b] "All Farms" data for corn differ slightly for the two samples because of three pairs in which farms were in adjacent counties.

in high value crops, especially corn and soybeans. The average and median value of crop output was higher on the conventional farms than on the organic farms in both years. The ratio of the value of crop output of the conventional to the organic group rose less between 1974 and 1975 than relative crop yields because corn and soybean prices declined somewhat in 1975, whereas the prices of roughages increased. This change favored the organic group because of their crop mix. In the past few years, both crop prices and weather conditions have been extremely variable in the Corn Belt, and future fluctuations in both will have important implications for the economic performance of the two kinds of farms we are studying.

Data on the variable costs included in the study for both groups, averaged over all cropland, are shown in table 5. Apart from general inflation in input prices, there were no significant changes from 1974 to 1975 in the overall average level or range of operating costs in the two samples. The difference in mean production costs ($19 per acre averaged over the two years) results primarily from the fertilizers and pesticides purchased by the conventional farmers (Lockeretz et al. 1975).

The difference between the value of crop output and variable costs, denoted here as crop production returns, is also shown in table 5. This measure was almost equal for the two groups in both years. As with the value of crop output, there is considerable variation within each sample, particularly the organic group. Because of this variation, and because of the sampling procedure mentioned earlier, table 5 should not be regarded as implying more than a qualitative relation between crop production returns on the entire populations of the two kinds of farms in

example, if organic farmers uniformly reported corn yields 20% higher than actual corn yields, then the average value of crop output per acre for the organic group would be biased upward by about 5%.

Table 5. Average and Median Market Value of Crops Produced, Operating Costs, and Crop Production Returns per Acre of Cropland

Soybeans (bu.)	32.6	34.7	27.4	51.4

the Midwest. It indicates only that this quantity on average is probably not very different between the two populations and could, of course, be very different between an individual farm of each type.

Various measures of the energy intensiveness of the two groups of farmers are shown in table 6. Whether energy intensiveness is measured in thousands of BTU's per dollar of crop output or thousands of BTU's per acre of cropland, in both years the conventional group was more than two times as energy intensive as the organic group. The main source of the difference between the two groups is the use of inorganic fertilizers, particularly nitrogen, by the conventional group. A contributory factor is the greater proportion of cropland in corn on conventional farms, which is more energy intensive than hay crops or small grains even apart from its fertilizer requirements, since it also requires propane for drying and a relatively large amount of fuel for field operations (Lockeretz et al. 1976).

Table 6 also presents measures of energy intensiveness for two crops, corn and soybeans, in thousands of BTU's per bushel of crop output. In the two years the conventional group was 2.7 to 2.8 times as energy intensive in raising corn. For soybeans the difference between the two groups was less pronounced; the conventional group was more energy intensive than the organic group in 1974, and the reverse was true in 1975. This change reflects the increase in soybean yields for the conventional relative to the organic group between 1974 and 1975 and a shift from slightly less to slightly more energy use per acre of soybeans for the organic group relative to the conventional group.

Table 7 shows the distribution of manure applications over various crops and the average application rates to those crops in the 1975 crop year. Manure spreading was a common practice on both groups of farms. The two groups were fairly similar in the prevalence of manure spreading, application rates, and the fraction of land receiving manure. However, from the information in this table and information above on acreage in cropland and animal units, one can see that the conventional group applied more manure to cropland although they had fewer animal units. This reflects the higher proportion of confined livestock on the conventional farms and the greater tendency of the organic group to keep livestock on temporary pasture or keep them in lots with access to pasture land. No data were collected on the nutrient content of the manure spread.

Finally, a calculation of the labor requirements for crop production in 1975 shows slightly higher labor requirements for the

[c] Weight as applied. Average for land receiving any manure.

organic group: 3.3 hours per acre for the organic farmers versus 3.2 hours for the conventional farmers or 19.8 hours per $1,000 of crop output for the organic farmers versus 17.8 hours for the conventional group.[15] The difference is more pronounced when expressed as labor input per dollar of crop output because the value of crop output per acre is lower for the organic group. A similar comparison of labor requirements for major crops shows equal average labor requirements for both groups for corn (3.8 hours per acre) and small grains (1.9 hours per acre). The organic group had a somewhat greater labor input for soybeans: 3.8 hours per acre versus 2.6 for the conventional group.

Conclusions

The results of this study are preliminary and largely qualitative. The organic farms produced somewhat less crop output per acre of cropland than their conventional counterparts; however, the variable costs of crop production per acre were higher for the conventional group. If fixed costs per acre did not differ between the two groups as assumed, then the net returns to crop production were about the same for the two groups. The organic group used considerably less energy per dollar of crop output and per acre of cropland and had slightly greater labor input per acre. By these measures the organic group appears to be doing reasonably well despite the fact that they do not use many of the chemical inputs that are generally regarded as key elements in the productivity and prosperity of modern agriculture.

Throughout this paper returns to cropping activity have been expressed in dollars per acre of cropland. A more relevant measure is returns to the whole farm enterprise, but this question cannot be addressed with these data. For crop production alone, the two groups had the same average gross returns minus variable costs per acre of cropland and, since the conventional group had an average of 39% more cropland per farm, their returns minus variable costs from crop production were also an average of 39% higher or 25% when adjusted for the difference in the average total size of the two samples. This calculation does not include income from grazing on permanent pasture. Because of the different ratio of cropland to total land in the two samples, as well as differences in livestock inventories, one cannot infer from these results that organic farming lowers the returns to crop production as a whole or to the whole farm enterprise, including livestock production. A determination of whether land is being put to its highest and best use in both groups of farms and a study of the joint crop-livestock enterprise would be required to answer these questions.

In the absence of a complete characterization of the land on each farm, one cannot assume a priori that the two groups are working with the same proportions of various kinds of land and are merely using that land differently. On the other hand, crop rotations that include hay are an integral part of the technology of organic farming, and this may limit organic farms to certain kinds of livestock operations and certain combinations of cropland and permanent pasture. Over time farmers have some control over the quantity of various kinds of land farmed within the constraints imposed by the availability of land and capital. Given this flexibility, the multiple uses to which land of a given quality may be put, and the unknown combinations of cropland and permanent pasture that are economic under the constraints of the technology of an organic farm, we presently have insufficient information to choose between three plausible explanations for the differing ratio of cropland to total size between the conventional and organic groups: (*a*) the two groups actually are similar in the characteristics of their land, but the organic farmers have to use some cropland as permanent pasture; (*b*) the two groups actually are similar in the characteristics of their land, but the conventional farmers are cropping land that the organic farmers consider more suitable as permanent pasture because it is subject to considerable erosion when cropped; or (*c*) the two groups differ in the character-

[15] The calculation is based on a uniform equipment and machinery complement representative of the kinds prevalent in both samples. As mentioned above, the two groups are very similar in the equipment they use. Since these groups were matched at least roughly by type of soil, a given operation, when performed by the hypothesized standard equipment, is assumed to take the same length of time on both groups of farms. In other words, results are intended to show the relative labor requirements of the two cropping systems under given soil conditions and with equipment of a given size and are not necessarily accurate in an absolute sense. Furthermore, the calculations deal only with labor required directly in crop production. No allowance is made for trips to town, general farm business, marketing, etc.

istics of their land, and the different cropland to total size ratios reflect appropriate land use in each case; e.g., the organic farmers need more permanent pasture and have acquired land that is best used as pasture.

Clearly, further analysis of land use on the two kinds of farms is necessary in comparing the two farming systems. Given this limitation of the present study, no basis exists for expressing crop returns data in terms of the entire farm. We have reported results on the basis of an acre of cropland, with cropland defined in terms of how the land is actually used. Additional data are needed on the land in each farm and the interaction of crop and livestock activities on organic farms before the two systems can be compared on a whole farm basis.

Other limitations should also be emphasized. We only compare farms that are mixed crop-livestock enterprises, and these are limited to the Corn Belt; the study has no implications for cash grain farming in the Corn Belt or farming of any kind in other regions. The number of farms studied was quite small, and the data are from only two crop years. Weather in 1975 was fairly typical of Corn Belt conditions, except for drought in the western portion of the study area, but the weather in 1974 was unfavorable for nearly every farm in the study. The organic farms studied had used organic methods for at least five years. Farms in transition from conventional to organic methods may encounter short-term fertility problems, since nutrients supplied in organic form are not as readily available as those in inorganic fertilizers. The extent to which the farms in this study import nutrients in the form of purchased feed was not calculated. In addition, organic farmers may be the recipients of positive or negative externalities associated with the insect and weed control practices of their conventional neighbors.

Even within the limits of the data collected for this study, there may be errors. The samples may not accurately represent the larger populations of farms from which they are drawn as a result of the manner in which they were selected. Errors may arise from reliance on farmers' reports of yields, field operations, purchased inputs, and other data used in the calculations. Also, the matching of conventional to organic farms was fairly crude. Therefore, the data cannot be used to infer the consequences of a significant portion of Corn Belt farms switching to organic methods, nor can they be used to predict the consequences of a switch to organic methods for an individual farm.

In addition, there are questions that relate to the long-run viability of both systems of farming such as nutrient balance, soil loss through erosion, and the organic matter content of the soil. We have begun research on some of these long-run questions but do not address those issues here.

These results, limited and qualitative as they are, suggest that further research is warranted into organic methods of crop production as well as methods that lie between the conventional and organic alternatives. Increased research effort on such alternatives, including controlled experiments, may ultimately yield high returns by increasing the range of acceptable and competitive methods for modern crop production and by facilitating the substitution of appropriate alternative methods in response to changing environmental regulations and energy prices.

Controlling Nonpoint Sediment Sources with Cropland Management: A National Economic Assessment

James C. Wade and Earl O. Heady

Utilization of cropland resources is one of the primary determinants of stream sediment water quality. The management of cropland is one way to improve sediment water quality. Models of the economics and physics of sediment provide insights into the agricultural production system and potential requirements for improved water quality. The application of such a model provides an assessment of the fundamental changes that might be required to accomplish reduced sediment loads through cropland management. The hypothetical water quality policies analyzed give insights into several possible sediment water quality policies.

Key words: land use, large-scale modeling, nonpoint pollution, sediment.

Sediment in streams is the most abundant of all U.S. water pollutants. Its impacts are widespread, and its controls are interwoven with land use and land use policy. Sediment causes pollutant damages estimated as high as $1 billion annually (Stall; Holt, Johnson, and McDowell). In addition, damages not directly accounted for by the market system include fish and wildlife environments, water recreation, and river and lake aesthetics overcome by sediment deposits. The damage process is so old that many view it as natural (Beasley).

This study is an evaluation of a modeling scheme designed to link demand for agricultural commodities to generation of cropland sediment (Wade). The evaluation takes the form of comparing five alternative policies to control sediment in the rivers and streams of the United States. The alternatives are designed to display the flexibility and limitations of U.S. agriculture in meeting environmental restraints placed on nonpoint sediment under a fixed set of demands for agricultural products.

James C. Wade is an assistant professor of agricultural economics, University of Arizona, and Earl O. Heady is a Curtiss Distinguished Professor of agriculture, a professor of economics, and the director of the Center for Agricultural and Rural Development, Iowa State University.

The Problem

The intensive cropping systems of the United States resulting from the technical transformation of agriculture utilize lands in an ever increasing number of ways. Intensive cropping practices resulting from the substitution of capital inputs for labor has resulted in increased application of chemicals to cropland in the forms of fertilizers and pesticides. The residuals of some of these chemicals combine with eroded soil and water runoff from cropland to pollute many of the streams of the United States (Beasley; Holt, Johnson, and McDowell). Simultaneous goals of meeting domestic and foreign food and fiber demands and meeting rising demands for a quality environment are forcing changes on the structure of agriculture. In viewing sediment from eroded cropland soils and its associated chemical pollutants as a residual of cropland management, environmental quality improvement may be attained by changing the use of land, the technologies applied to the land, and the crops produced on it. The process viewed as a local problem has many simultaneous interregional and na-

tional implications. The changes in agricultural crop production in one region of the country to meet water quality demands require adjustments in production technologies not only in that region but also in other regions to provide the demanded agricultural products. The adjustments in the agricultural production system that result from national environmental quality sediment goals are the concern of this study.

The Model

The model used in analyzing the national and interregional impacts of sediment water quality on the agricultural system is described in equations (1) through (8):

$$\min Z = c'x \tag{1}$$

subject to

$$Ax \leq b, \tag{2}$$

$$Bx \geq d, \tag{3}$$

$$Sx - Dx_D \leq s^*, \tag{4}$$

$$x_D - Tx_T \leq 0, \tag{5}$$

$$x \geq 0, \tag{6}$$

$$0 \leq x_D \leq r_D, \tag{7}$$

$$0 \leq x_T \leq r_T, \tag{8}$$

where x is commodity and sediment production vector, c is production costs vector, A is resource requirements matrix, b is resource limits vector, d is commodity demands vector, B is commodity output transformation matrix, S is soil loss matrix, x_D is sediment delivery vector, x_T is sediment transport vector, D is sediment delivery ratios matrix, T is sediment transport ratios matrix, r_D is restraint vector on delivery sediment, r_T is restraint vector on transported sediment, and s^* is a vector of erosion from noncropland sources.

This statement of the model is simplified to express its central elements without giving complexity to each component involved. Detailed descriptions may be found elsewhere (Wade, Meister and Nicol).

Individual sections of the model can be described in simple terms. Equation (1) is the total cost function for agricultural production. It includes costs for crop and livestock production and for commodity transportation among the various regions of the United States. Equation (2) is the resource transformation matrix system, which converts the resource vector (b) into the agricultural commodities demanded through equation (3) from the final demand vector (d). Both resources and commodity demands are regionally differentiated. Equation (4) is the sediment delivery relationship that determines the quantity of sediment moving from each subriver basin. The transport of sediment among the subriver basins modeled is represented in equation (5). Equation (6) represents nonnegativity in production of agricultural commodities. Finally, equations (7) and (8) represent environmental restraints on sediment delivery and transport from the various regions. Some additional details about the various sections of the model are given in the following paragraphs.

The Production Sector

The basic commodity production and transportation systems of this model were developed as an analytical tool for use in the National Water Assessment for the Economic Research Service, U.S. Department of Agriculture, and the Water Resources Council and are specifically described elsewhere (Meister and Nicol, Wade). For this presentation, however, a brief verbal description of the production mechanisms will provide a background for the analysis that follows.

In this model crop production occurs in each of the 105 producing areas, each of which is made up of nine land quality classes. Each region is provided activities that produce crops occurring historically in the producing area.[1] The crop commodities produced by such activities are shipped interregionally to meet the demands of each of twenty-eight market regions (Meister and Nicol). Production technologies available in each producing area include a range of crop rotations, tillage practices, and conservation practices for each soil class.[2] Crop production activities require land, water (for irrigated activities in the western states), nitrogen fertilizer, and operating costs as inputs. Each activity produces an average yield of the crops in the rotation based on the technical

[1] Endogenous crops are barley, corn grain, corn silage, cotton, lint and seed, legume hays, nonlegume hays, oats, sorghum grain, sorghum silage, soybeans, sugar beets, and wheat. Resources for the production of all other crops are preallocated in each producing area.

[2] Tillage practices are conventional tillage residue removed, conventional tillage residue left, and minimum or reduced tillage. Conservation practices are straight row, contour, strip, and terrace cropping.

and cultural practices and the characteristics of the producing area and residual soil loss based on regional climatic and soil conditions. Nitrogen carry-over is computed for nitrogen-fixing crops. The soil loss for each activity is computed using the Universal Soil Loss Equation (Wischmeier and Smith) and data provided by the Soil Conservation Service (Nicol). Costs for producing one acre of a cropping activity consider crop yields, the tillage and conservation practices used, and the producing area in which production occurs.

Livestock production, defined at the market region level, includes dairy, hogs, beef cows, and beef feeding, which provide five commodities: milk, pork, beef feeders, fed beef, and nonfed beef.[3] Various ration alternatives are used in each market region to transform feed inputs into livestock outputs at lowest cost. All technologies and feed conversion rates for the crop and livestock production are projected to year 2000. Production costs are computed based on 1972 average input costs in each producing area, assuming that relative input costs will remain unchanged to year 2000. Although this assumption is somewhat limiting, the inability to estimate potential long-term changes in price relationships makes this assumption as good as any other and gives a sound base for comparison of results in the modeled system (Meister and Nicol).

[3] Other livestock and poultry production is allocated based on historic production levels. The demands for feed inputs are computed and added to total market region demand.

Demand and Market Sector

National demands for the various commodities of the model are based on a projected national population of 264.3 million in 2000 as shown in table 1. Regional distribution of population among the market regions and export levels are set as in the National Water Assessment model (Meister and Nicol, U.S. Water Resources Council). The commodities—corn grain, barley, oats, oilmeal (from soybeans and cotton), sorghum grain, wheat, milk, pork, beef feeders, fed beef, and nonfed beef—are shipped among the market regions to meet consumer and export demands, while cotton lint and beet sugar are consumed nationally. Hay crops and silage (from corn and sorghum) are consumed within the market region of production as required by the livestock production systems and exogenous livestock.

Table 1. National Commodity Demands for National Sediment Model Year 2000

[a] Negative numbers indicate net supplies exogenous to the model.

Sediment and Erosion Sector

Three types of erosion sources are considered in this study. First, erosion from cropland used in production is determined as the sum of the soil loss from all cropping activities in each producing area. Second, soil loss is computed from croplands not used in crop production. Finally, erosion from all noncropland sources is fixed since managing of noncropland is not possible under the assumed model. The total erosion from noncropland sources includes estimates for gully, stream bed, and channel erosion. The procedures used to determine the erosion rates are described in detail in other publications (Wade, Wade and Heady).

The movement of eroded soil from its original resting place to the stream system is a process called sediment delivery. Sediment delivery is assumed in this study to be a fixed proportion of the total gross soil loss from all sources within each producing area, both fixed and variable (cropland). The sediment delivered from each producing area joins the sediment delivered from other producing areas in a flow pattern that simulates the river system of the United States. The eighteen major river basins serve as summary regions for data analysis of the model solutions.

The sediment delivery and transport system described previously in equations (4) and (5) is expressed for the ith producing area by equations (9) through (11). Sediment delivery from the ith producing area is

$$(9)\quad D_i\Big[\sum_j \sum_k S_{ijk}X_{ijk} + s_i^* + \sum_j SA_{ij}XA_{ij}\Big] = XD_i,$$

where X_{ijk} is acres of production activity k on land quality class j, S_{ijk} is tons per acre of gross soil loss from activity k on land quality class j, s_j^* is tons of gross soil loss for land uses not endogenous to the model, XA_{ij} is acres of unused cropland in land quality class j, SA_{ij} is tons per acre of gross soil loss from unused cropland of class j, D_i is proportion of gross soil loss that reaches the stream, and XD_i is tons of suspended sediment delivered.

Similarly, sediment transported for the ith producing area that has sediment flow-through is

$$(10)\quad T_i\Big[\sum_{l\to i} XD_l + \sum_{k\to i} XT_k\Big] = XT_i,$$

where XD_l is sediment delivered from the lth upstream producing area directly, XT_k is sediment transported through an upstream producing area k into the stream producing area l, T_i is proportion of sediment moved to producing area i's boundary, which is transported through producing area j, and XT_i is sediment transported.[4] Finally, the total sediment load ($XS_{i'}$) at the outflow of each river basin is

$$(11)\quad XS_{i'} = XT_{i'} + XD_{i'},$$

where $XS_{i'}$ is the sum of sediment delivered from the sediment transported through the last (or ith) producing area of the river basin.

This formulation of the erosion and sediment delivery system requires the computation of sediment delivery and transport coefficients (see Wade for details of coefficient development). The sediment delivery coefficients vary substantially among the producing areas with the highest ratios of 32.2% and 37.8% of eroded soil delivered to the stream system occurring in a subarea of the Upper Missouri River Basin and the Klamath River of northern California. Low sediment delivery ratios of less than 1% of the total sediment delivered to the stream occur in several areas of the country but dominate in areas of the southeastern states and in some high mountain areas. Since these coefficients are estimated from historic data, the differences in geographic, geologic, and economic make-up of each region should be reflected in each coefficient. Similarly, the sediment transport ratios are estimated for each producing area that has upstream rivers flowing through. These coefficients vary from 100% for river segments like the Lower Mississippi, which is channelized with few sediment trapping areas, to 0.1% for area river segments like the Lower Tennessee River, which has a series of large reservoirs. Coefficients for the middle parts of the Mississippi River, which has numerous locks and dams, range from 40% to 70% of the sediment load transported through the region.

Converting equations (9) through (11) into linear restraints and adding them to the linear programming production model described previously gives the link between agricultural land management and sediment loads as a water quality variable.

[4] The symbolism $l \to i$ and $k \to i$ means "for all l (or k) contributing directly to i."

Concept of Alternative Futures

The formulation of an analysis procedure that incorporates a normative model potentially produces some misunderstandings. The normative model of national cost minimization creates a diversion from current reality as short-term restriction imposed by various institutional and physical restraints are ignored to view more fundamental long-term relationships. Obviously, in a model such as the one presented here, some variables that are extremely important in the short run are omitted and, thus, assumed perfectly flexible in the long run. For example, regional restraints on available labor and capital are not included in this model, as these variables are assumed to be completely mobile between the present and the year 2000. Utilizing the year 2000 allows enough time for the long-term changes necessary to establish a new economic equilibrium to take place.

Formulation and examination of alternative policies in this type of framework are considered as an analysis of alternative prospects for the future (or alternative futures), remembering that the model is only an approximation of reality and not reality. This is particularly a problem in a model that formulates an evaluation procedure that combines economic and physical data. One must remember that the relationships are casual but, as such, are a first-order approximation of a problem more often viewed as either a physical or an economic problem but not both.

The solutions presented in this paper represent a set of five alternative futures. Comparing these alternatives to the past or the present serves only to confuse, since by its normative nature and long-run assumptions the model will not approximate either. Comparisons of alternative futures must be made among a set of alternative futures with only informal looks at the past. These looks back serve as guideposts and intuitive points of departure. Analysis of alternative futures examines the departure of those futures that incorporate policy alternatives from the unrestricted future.

Policy models are neither forecasts nor predictions. They are analytical tools for assessing the possible impacts of variations in policy. In the analysis that follows we analyze five alternatives in such a manner.

Solutions Analyzed

Five national sediment control policies were evaluated using this model. Each examined the changes in U.S. agriculture resulting from the regulation of sediment loads. An unrestricted alternative was run with no restraints placed on sediment movement or loads in the stream system. This solution provides a base for comparison with alternatives where sediment restraints are imposed. A second alternative minimizes the total national sediment load and total production cost,[5] which is accomplished in two computer runs by first running the model to minimize the total national sediment load. The minimum sediment load is then used as an upper limit on total national sediment load (and also as a lower limit), while total cost is minimized. Thus, minimum sediment loads at minimum cost are obtained. The minimum sediment alternative provides an extreme environmental restraint where maximum stream quality is obtained while meeting prespecified consumer demands. This policy is used only for comparison purposes and is not proposed as a practical or administratively feasible alternative.

The third alternative examines the effects of a policy that restricts the average annual soil loss allowed per acre for each producing area and soil class. Production technologies for each soil class having average soil loss rates that exceed the maximum level allowable to conserve the soil and maintain its productive capacity are eliminated from the set of technologies available for crop production. Limiting soil loss in this manner removes many of the low cost but non-soil conserving practices that would otherwise be used. This policy, the T-limit alternative, is a simulation of the Iowa Conservancy Law applied to the forty-eight contiguous states. The T-limit alternative as applied in the Iowa legislation requires farmers who have gross annual cropland soil loss higher than the maximum allowed in their county to initiate operations to improve the soil loss condition. The legislation also required that federal subsidy funds be available to help the farmer provide the conservation treatments needed. With the reduced availability of funds and

[5] Total national sediment load is the sediment loads flowing from all rivers into the ocean and countries surrounding the United States.

the general policing problem, the legislation has had little affect on farming operation. If such a policy is to be applied on a national scale, the problems of policing and subsidation would have to be overcome.[6]

The fourth alternative is the PA-limit alternative, which restrains sediment loads from cropland for each producing area to 20% less than the unrestricted alternative. This solution examines some of the potential variations in location of production and technical management of cropland that would reduce sediment load.

Although this alternative does not express a currently proposed alternative, the types of alterations in management of cropland can be related to a set of policies that could be supported by water quality and farming interest. Once a target level is established for sediment loads in the rivers or streams flowing from each subbasin or producing area, land use goals or practices can be induced by providing cost sharing funds to producers under stipulations that such funds be used in a prescribed manner or by establishing a taxing scheme for eroded soil moving from the land and into the stream system.

Determining such tax rates is a highly information-intensive operation. Establishing tax rate or penalties for eroded farm land could be based on research materials concerning soil loss and sediment transport in water. Neither data presented in this report nor most other currently available are adequate for making such judgments. A considerable amount of additional research would be required to integrate the physical and policy concepts. Subsidization programs could be similar to already existing small watershed projects that combine land use change and stream impoundments to reduce sediment problems. The water quality management program would be increased to administrative areas conforming to subbasins or producing areas and the much broader water quality goals.

[6] The Iowa Conservancy Law was initiated to control erosion and conserve cropland farming potential. However, by keeping soil on the cropland, such a program also reduces the movement of sediment into the stream system. The law is administered by local conservancy boards who hear complaints from adversely affected parties and make judgments on improvements required to reduce damage to the cropland and to adversely affected parties (generally, neighbors upon whom sediment is washed). Actual soil loss rates are based on the research materials presented in Wischmeier and Smith, while the allowable rates are determined considering the maximum rate at which soil can be lost without affecting the productivity of the soil (Iowa Cooperative Extension Service).

Finally, a river basin limit alternative requires a 20% reduction in the sediment loads from cropland below the unrestricted alternative at each river basin outflow rather than at the producing area level. This policy is similar to the PA-limit alternative except that the regions of concern are much larger. To enforce such policies, a group similar to the River Basin Commissions would be required. Such agencies would have to have interstate power to examine policy goals and to provide the guidelines for meeting the goals. The results of this analysis provide insights into some of the required guidelines, which would have to be expanded into more specific regional policy statements by such a commission. Once such goals and guidelines are established, either a policing or incentives type administration could be used to obtain required objectives. Since policing is very costly and is politically unpopular, the latter approach seems more feasible. The guiding group or agency could use differentiated policies among the various subbasins within the basin to obtain desired water quality goals.

Results

Sediment Loads

Table 2 presents the sediment outflows of the eighteen major river basins of the United States for each of the five alternatives. These outflows are compared with the estimated average annual sediment loads for 1960–69 to varify the general magnitude of the simulated sediment loads of the unrestricted alternative. The sediment loads for the unrestricted alternative compare with the estimated average loads (see Curtis, Culberson, and Chase) except for a few notable cases where cropping patterns are significantly different in the year 2000 than at the present. For example, sediment loads of the Upper Mississippi River and Missouri River basins differ substantially from the average historic values. However, the combined flows moving from the Mississippi River do not differ greatly from historic values. Two distinct mechanisms create the differences in these two river basins. First, the use of reduced tillage cropping practices in the Upper Mississippi River Basin reduces the erosion substantially even in the unrestricted alternative. In the Missouri River Basin the large acreage

[b] Used to compute total sediment outflow to the oceans surrounding the United States.
[c] Not available.

of unused cropland erodes at higher than average rates, producing more residual than if the land were cropped. This rate assumes that cropland is simply dropped from production and that no attempts are made to maintain the soil of the uncropped land. In the long run, some areas would revert to natural vegetation reducing the soil loss from unused land. However, in many parts of the country without conscious programs to revegetate such lands, erosion rates would be very high.

The total sediment outflow from the United States approximates the historic average value as do most of the sediment loads of the individual river basins. The sediment loads for the unrestricted alternative provide a basis for comparison as restraints are placed on sediment loads. For the minimum sediment alternative, sediment loads are reduced sizably as the national total load is reduced. The total sediment load is reduced by 23.3% from the unrestricted alternative. This reduction is complicated by the fact that 308.3 million tons of the total sediment load originate from noncropland sources and cannot be altered by changing cropland use. The agricultural portion of the sediment load is reduced by 90.6% from the unrestricted to the minimum sediment alternative.

The impact of noncropland sources of erosion varies among the river basins. The largest proportion of total erosion from noncropland sources is in southwestern United States, where between 93.1% and 98.3% of the total unrestricted alternative's sediment loads are from noncropland. In contrast, in the Midwest larger proportions are from cropland sources. Although this result is not surprising, it is extremely important that the regional differences in the impact of potential land use policy are directed solely at cropland management.

The T-limit alternative, which restricts cropping methods available to farmers to those that produce no more than maximum soil loss level, results in sizable changes in sediment load for most river basins. The highly erosive areas of the Midwest and Southeast have sharply reduced sediment loads. The cropping areas of the West are less restrained since rainfall is low and thus soil loss from cropland is much less than in other areas. Some areas of the West actually

show an increase in sediment loads as cropping adjustments necessary to meet commodity demands are made. The national total sediment load decreases to 376.5 million tons per year, a 9.3% reduction from the base solution.

The PA-limit alternative offers a third environmental alternative obtained by requiring a reduction in the sediment load of each subriver basin or producing area without restricting the technologies. This alternative results in a 5.1% national reduction in sediment loads as compared to the base solution. This national reduction occurs as each river basin's load is reduced and each affected subbasin limit works its way through the river system. The river basins with the largest reductions are naturally those that have the largest proportion of cropland sediment sources. Thus, the sediment loads do not substantially change in the Southwest where cropland contributions are small.

Sediment loads for the river basin limit alternative are almost identical to those of the PA-limit alternative, producing only a 5.1% reduction in national sediment load. However, since the restrictions on sediment loads are placed at the river basin level rather than the producing area level, major differences occur in the use of the land and the cost of sediment load reductions.

Land Use

One of the keys to the control of sediment as a nonpoint source of pollution is the use to which cropland is placed. Cropland is the management tool in this evaluation of sediment loads, since land use is a determinant of the soil loss and eventually the sediment load of each region. An analysis of four primary areas of cropland use are briefly described below: tillage practice, conservation practice, crop type, and total use. These variables are summarized in table 3 for the year 2000.

Land use for the minimum sediment alternative is significantly changed from the unrestricted alternative. The most noticeable change is in the use of reduced tillage technologies and terracing practices to reduce soil loss. Other significant changes include increases in close-grown hay crops.

Table 3. National Total Acres of Cropland by Conservation and Tillage Treatments and by Crop Type for the Alternatives for Sediment Control

[a] Totals may not add because of computer rounding.

Such changes require additional total acreage to produce the commodities demanded. Terracing acreages increase by a dramatic 389.3% over the unrestricted alternative. These extreme environmental restrictions also alter production systems and the location of primary production. Significant increases in economic advantage are noted in the western river basins.

Similar but less dramatic changes are required in land use for the T-limit alternative. Terracing acres increase by 121.7% over the unrestricted alternative, while reduced tillage acreage increases only 11.5%, compared to the 90.6% increase in the minimum sediment alternative. Rather small changes in land use are noted between the unrestricted alternative and the producing area and river basin limit alternatives. The changes in land use for the PA-limit alternative reflect the impositions of restraints at levels that demand change within each producing area without regard to similar changes that may be occurring in other producing areas of the same river basin. In the river basin limit alternative, intrabasin trade-offs in production are utilized to balance required water quality changes. Thus, river basin level summaries do not fully express the location changes in production that occur to meet environmental changes. In the PA-limit alternative sediment loads decrease almost uniformly for all producing areas, since the restraints are placed at the producing area level. These decreases are from 1% to 20%, depending on the proportion of the total land area cropped. For the river basin limit alternative, the sediment loads increase in some producing areas and decrease in others, since some producing areas that are at a comparative economic advantage produce crops intensively. In these areas, total erosion increases, while conservation and tillage practices are used to reduce sediment loads in other areas of the same river basin. This adjustment process utilizes some producing areas as "water quality management areas," and the total river basin sediment load is reduced at lower cost than in the PA-limit alternative. Thus, although on a producing area level cropland use is changed markedly, this change is not reflected in the river basin level sediment loads of table 1.

Sediment loads for each producing area vary in the river basin limit alternative. Changes in sediment load from the unrestricted alternative range from small increases in several areas to greater than 40% changes in other areas. While many of the crop-producing areas of the Midwest and Great Plains are essentially unchanged from the unrestricted alternative, producing areas in the same river basin decrease substantially to meet the river basin level restraint. In the Upper Mississippi River Basin, Great Basin, and Upper and Lower Colorado River basins, sediment loads in each producing area are reduced a small amount (less than 1%) to reduce the river basin sediment load to the required level. Utilization of croplands determine these changes in sediment loads.

Crop composition differs considerably between the unrestricted and minimum sediment alternative as illustrated in tables 4 and 5. Production of row crops, although rather stable in acreage, changes in composition under the minimum sediment alternative as more corn and sorghum grain are produced and less (almost no) silage is raised, since silage production removes crop residue and increases erosion. To augment grain inputs in the livestock-feeding system, increased hay and small grain acreages are used for feed.

Cost of Sediment Control

One of the primary items of concern in analyzing potential environmental policy is the evaluation of costs sustained by farmers and by society. Table 6 presents differences in total national cost of meeting consumer demands under the several alternatives.[7]

The costs of producing the total bill of goods assume a fixed final demand for commodities, which creates some difficulty under the extreme variations of this model since consumer demands are not fixed as prices change. In the context of analyzing sediment control policy, fixed commodity demands are a limitation to this type of model. The exact division of the cost of sediment control among consumers, producers, and society as an institution is unclear. The costs of table 4 represent the change in the total (private plus social) costs under the assumed policies. The costs of the various alternatives could be represented by changes in marginal cost of producing each commodity or as the social

[7] Total cost is the cost of producing and transporting all crop and livestock commodities endogenous to this national model exclusive of land rent.

subsidies required to maintain the marginal cost of the unrestricted alternative or both. In the T-limit alternative, the marginal cost of producing the commodities follows a normal pattern of increasing as returns to land among the farmers increases and a long-run adjustment is made by a somewhat natural market adjustment, and all cost changes can be passed on to consumers. When regional restraints on sediment loads are imposed, such as the minimum sediment, PA-limit, and river basin limit alternatives, numerous

Table 6. Total Annual Cost of Producing and Transporting Commodities for the Five Sediment Control Alternatives

	Unrestricted	Minimum Sediment	T-Limit	PA-Limit	River Basin Limit
Total cost (million $)	31,932	45,332	32,863	32,034	31,958
Increase in total cost (million $)	—	13,400	931	102	26
Index of total cost	100.0	142.2	102.9	100.3	100.1
National sediment load (million tons)	415.0	318.3	376.4	393.7	393.7
Decrease in sediment load (million tons)	—	106.7	38.6	21.3	21.3
Index of total land	100.0	76.7	90.7	94.9	94.9

inefficiencies are forced into the production system as farm practices are forced to meet stream sediment quality requirements. Cropland is used at levels other than at marginal rates of return, and losses are incurred by producers in some areas and not in others. These losses result in decreased marginal costs for most commodities and decreased long-run consumer costs. If society is going to support such policies, the losses of the farmers would need to be compensated to provide income parity and a continued strong farm sector. The results are lower food cost to consumers and higher environmental budget cost to entice a pattern of land use that will meet prespecified sediment water quality goals. The question of who pays depends on the policy and how it is administered.

For the minimum sediment alternative, total costs increase by 42.2% above the unrestricted alternative or $13.4 billion annually. This extreme environmental control provides a 23.2% reduction in total sediment load. The T-limit alternative has total costs of $931 million, 2.9% less than under the unrestricted alternative. The corresponding reduction in total sediment load of 9.3% is large relative to the total cost change.

In the PA-limit and river basin limit alternatives, total cost changes are small, only 0.3% and 0.1%, respectively, relative to the unrestricted alternative. However, both obtain a 5.1% reduction in total sediment load. In these two cases, the point of application of the restraint is extremely critical in determining total cost. As illustrated in table 2, almost identical sediment loads are obtained by the two at both the river basin and national levels. Obviously, at the more detailed level of the producing areas, much more variation is shown in sediment load.

Limitations

This model is limited in its ability to duplicate the total environment of sediment water quality policy. As a linear programming model, it suffers some of the typical restrictions on such models. The limited response of the demand sector to variations in marginal production cost limits the analysis in that the specific consumer commodity demands and environmental policies analyzed are not simultaneous. This same problem exists to some extent for the production sector as variations in production will obviously change the demand structure for production inputs. Input prices are assumed to maintain the same relative input costs. The marginal cost of the commodities must, therefore, be considered as relative costs to be compared with cost of other alternative futures. On the physical side of the model the representation of the sediment system is an elementary approximation that may introduce irregularities into the policy analysis and formulation. For example, estimation of soil loss rates are not uniformly accurate across the United States, and the procedure for estimating sediment delivery and transport ratios are at best crude. These are first-order approximations of the variables of sediment water quality and, like all other variables and assumptions of this model, if in error may seriously modify the findings of this study. However, they may also point toward a better understanding of the physical research needed to augment policy decisions and, in doing so,

point biological, physical, and economic researchers toward new areas of cooperative research.

Conclusions

The alternatives examined in this analysis give no best sediment control policy. Clearly, the minimum sediment alternative requires extreme changes in the production system that increase total production cost greatly. This solution requires many interregional changes to accomplish sediment goals. However, the principle burden falls on the Mississippi River drainage area where the potential erosion control is greatest. In this alternative, as in all of the others, erosion from noncropland sources exceeds that from cropland sources. Cropland remains a major source of sediment, and cropland management offers a means for improvement in water quality.

The T-limit alternative places controls at the farm level and increases both the average and marginal costs of the commodities produced. It also results in a substantial reduction in total sediment load. Regional erosion differences are recognized by this type of control and economic advantages change accordingly. If a higher level of sediment control is desired, this type of policy might prove difficult to administer.

The final two alternatives, the PA-limit and the river basin limit alternatives, do not provide a large change in the national sediment load. They do, however, provide some insight into the type of variation in sediment loads and production cost expected under the two alternative levels of administrative control.

The optimum policy of sediment control based on cropland management can only be determined by evaluating society's goals relating to food costs, environmental quality, farmer decision freedom, and other dimensions of resource use. The use of large-scale models, such as the one outlined in this study, to design policy might substantially reduce the costs of policy choices to society by anticipating the interactions and costs of such policies. To the extent that such models are improperly formulated, policy implications may be wrongly stated. In any event, additional information provided by policy modeling is a needed input for policy formulation.

The Welfare Effects of Erosion Controls, Banning Pesticides, and Limiting Fertilizer Application in the Corn Belt

C. Robert Taylor and Klaus K. Frohberg

The partial welfare effects of alternative erosion control methods, banning insecticides, banning herbicides, and limiting nitrogen fertilizer in the Corn Belt are examined. The estimated welfare effects are partial since they reflect the change in consumers' plus producers' surplus arising from the production and consumption of corn, soybeans, wheat, oats, hay, and pasture but not the environmental benefits associated with pollution abatement or the administrative and enforcement cost of the policies. A large linear programming model of crop production in the Corn Belt was used to make the estimates.

Key words: Corn Belt, erosion, linear programming, models, nitrogen fertilizer, pesticides, pollution.

The 1972 Federal Water Pollution Control Act mandates the development and implementation of controls of agricultural nonpoint sources of water pollution (U.S. Congress). The primary responsibility for carrying out this mandate rests with state governments, with the Environmental Protection Agency's (EPA's) role being one of seeing that this is done in a satisfactory manner. The EPA currently believes that in many cases the goals of the act can be carried out by applying practicable best management practices, including conservation practices that prevent or mitigate entry in the nation's water of diffuse-source substances that tend to degrade those waters. In those cases where applications of these management measures are inadequate to attain or maintain water quality, the EPA intends for more vigorous controls to be implemented (Pisano, p. 11). If the goal of the act that "the discharge of pollutants into the navigable waters be eliminated by 1985" is strictly interpreted, the more vigorous controls seem likely for many agricultural nonpoint sources (U.S. Congress, section 101.a).

This article presents estimates of the partial welfare effects of the following public policies related to agricultural pollution in the Corn Belt: (*a*) a ban on the use of herbicides; (*b*) a ban on the use of all insecticides; (*c*) nitrogen fertilizer restrictions of 100 and 50 pounds per acre; (*d*) no straight row cultivation; (*e*) gross soil loss restrictions of two, three, four, and five tons per acre; (*f*) terracing subsidies at annualized rates of \$5, \$10, \$15, \$20, and \$40 per acre; and (*g*) gross soil loss taxes of \$4, \$2, \$1, and \$0.50 per ton. The pesticide and nitrogen policies, while extreme, are plausible under a strict interpretation of the 1985 water quality goals that are set out in the amended 1972 Federal Water Pollution Control Act. The pesticide regulations that are presently under consideration by the EPA and states will not significantly affect the crops considered here and were not evaluated. Illinois, the only Corn Belt state to seriously consider limiting fertilizer use, has determined that nitrates are not presently a problem and has recommended that controls

Technical Article No. 12818 of the Texas Agricultural Experiment Station. This publication was supported in part by a grant from the Rockefeller Foundation to the University of Illinois on "Nitrogen as an Environmental Quality Factor" and a grant from the Environmental Protection Agency (No. 68-01-3584) titled "Economic Evaluation of Implementation Strategies for Control of Agricultural Non-Point Sources of Water Pollution." With the usual caveats, thanks are due to C. B. Baker, Steve Sonka, and E. R. Swanson for their critical comments.

not be instituted at this time. But since some water supplies to the state exceed the controversial U.S. Public Health Service standard for nitrates, this issue is by no means resolved. The magnitude of the nitrate problem in other states is not well known. Erosion-sedimentation controls are much more likely to be implemented than pesticide bans and fertilizer restrictions and therefore constitute the practical thrust of this article.

While the primary responsibility for nonpoint source management rests with states, the federal government retains the authority to impose more stringent requirements. Furthermore, the EPA is charged with encouraging uniform state laws relating to the prevention, reduction, and elimination of pollution (U.S. Congress, section 103.a). For these reasons and also because of the large number of conceivable policies that differ by state or region, this analysis focuses on regionwide policies.

The estimated effects are partial in the sense that they reflect the change in consumers' and producers' surplus arising from the production and consumption of the major crops but not the environmental benefits associated with pollution abatement or the administrative and enforcement cost of the policies.

The Model

The model used for this analysis is a linear programming model of the production and marketing of corn, soybeans, wheat, oats, hay, and pasture in the Corn Belt. The production of cotton and soybeans in this area accounts for about 70% and 60%, respectively, of the total U.S. production of these commodities.

The objective function of the model is consumers' plus producers' surplus in the corn and soybean markets minus the total variable costs of producing a specified amount of small grains, hay, and pasture. As is well known, the maximization of surplus gives a competitive equilibrium solution (Takayama and Judge).

The demand functions for corn and soybeans are incorporated into the model in a stepwise fashion, with steps in 2¢ increments. The demand functions used in the model are

$$(1) \quad Q^c = 5{,}613{,}712{,}245 - 763{,}775{,}100P^c$$

and

$$Q^s = 1{,}469{,}981{,}594 - 130{,}224{,}637P^s,$$

where Q^c and Q^s are the bushels of corn and soybeans demanded, respectively, and P^c and P^s are the per bushel prices. At the mean, the elasticity of demand for corn is -0.50, and the corresponding figure for soybeans is -0.64. These demand functions were subjectively specified after reviewing recent demand analyses (Houck, Ryan, and Subotnik; Vandenborre; Brandow; Rojko, Urban, and Naive). The quantities of wheat, oats, hay, and pasture demanded were treated as constants in the model because these are relatively minor crops in the area and also because the inclusion of stepped demand functions for them would have increased the size of the model to the point where the cost of obtaining a solution would have been prohibitive.[1] Fixing the quantities demanded of the minor crops causes a slight over or under (depending on the policy) estimation of the change in surplus resulting from the policies.[2]

The land base for the area modeled was divided into eleven land capability units (LCU's) within each of seventeen geographical regions that are land resource areas (LRA's) defined by the Soil Conservation Service (SCS) (USDA 1975). Crop production activities in the model differ by crop rotation (an average of about eleven rotations for each LCU within each LRA), conservation practices (straight row, contouring, and terracing), and tillage methods (fall plow, spring plow, and chisel plow). Rotations rather than just single crop activities are

[1] Hay and pasture account for about 27% of the acreage in the area. In the benchmark model solution as well as in actuality, hay and pasture are primarily produced on LCU's that are unsuitable or marginally suitable for row crop production. To the extent that wheat and oats are grown to diversify production and reduce risk, the inclusion of their production in the model as constraints is reasonable. The quantity of hay and pasture that had to be produced was specified by LRA, while the quantity of wheat and oats demanded was specified for the whole Corn Belt area.

[2] The change in consumers' surplus (ΔCS) was defined to be

$$\Delta CS = \sum_{i=1}^{6} \Delta CS_i,$$

where ΔCS_i is the change in consumers' surplus for the ith crop, with $CS_i = (P_{Bi} - P_{Ri})(Q_{Bi} + Q_{Ri})/2$, where i is corn or soybeans and $CS_i = (P_{Bi} - P_{Ri})Q_{Bi}$ where i is wheat, oats, hay, or pasture, P_{Bi} is price for crop i in bench run, P_{Ri} is price in model run for the policy under consideration, Q_{Bi} is quantity demanded for crop i in bench run, and Q_{Ri} is quantity demanded in model run for the policy under consideration.

included in the model to reflect the influence of the previous crop on the fertilizer and pesticide requirements of the current crop.

A simplified matrix representation of the model is given in table 1. The first column of this matrix represents 14,542 crop production activities. The vector C represents the per acre variable production costs exclusive of labor and fertilizer, while the vectors Y^c, Y^s, Y^w, Y^o, and Y^h give the yields associated with each activity. Each production activity takes one acre of land from the appropriate LRA and LCU (see row 11) in the appropriate LRA and LCU. The vector *nsc* gives the carry-over nitrogen supplied by soybeans to corn in a rotation. The vectors *nw*, *no*, and *nh* give the nitrogen required for wheat, oats, hay or pasture, respectively. For a given land type and conservation practice, a single production activity is set up for hay and pasture. This production can either be transferred to pasture (column 17) or baled for hay (column 16).

The second set of columns in the matrix in table 1 represent two steps on a stepped demand function for soybeans. These steps are

$$(2) \qquad P_1^s \text{ if } 0 \leq Q^s \leq Q_1^s \text{ and}$$
$$P_2^s \text{ if } Q_1^s \leq Q^s \leq Q_2^s,$$

where P_i^s is price of soybeans for the ith step, Q_i^s is maximum total quantity of the soybeans that will be purchased at the ith and higher prices with $P_1^s > P_2^s$. Each of these activities draws from the soybean production, as is indicated by the -1 coefficient in row 5. The soybean demand step constraints (rows 22 and 23) reflect the inequality shown in equation (2) above. For simplicity, only two steps are indicated in the matrix in table 1; the model contains seventy-five such steps.

The fourth, fifth, and sixth set of columns in the matrix in table 1 together represent steps on a demand function for corn and, for each respective corn-nitrogen fertilizer price ratio, represent steps on a fertilizer response function for corn; that is, the model calculates the optimal fertilization rate and associated yield for each market price.

Before considering this matrix formulation, consider the special class of response functions for which it applies. This class, used by Illinois agronomists to tailor fertilizer recommendations to individual situations (Illinois Cooperative Extension Service), is one for which the optimal per acre nitrogen fertilization rate is given by multiplying the maximum yield obtainable (for a given level of nonfertilizer management) times a factor that varies with the price ratio but not with the basic soil productivity level. The figures used as a basis for this study are given in column 2, table 2. These optimal nitrogen factors imply points on a response function. The points, expressed on the basis of percentage of maximum yield, are shown in column 4, table 2. The phosphorous and potassium fertilizer application rates are assumed to be equal to the amounts of these nutrients removed in the grain. This should approximately maintain the P and K levels in the soil (Illinois Cooperative Extension Service).

The steps on the demand function considered here are

$$(3) \qquad P_1^c \text{ if } 0 \leq Q^c \leq Q_1^c \text{ and}$$
$$P_2^c \text{ if } Q_1^c \leq Q^c \leq Q_2^c,$$

where P_i^c is price of corn for the ith step and Q_i^c is maximum total quantity of corn that will be purchased at the ith and higher prices with $P_1^c > P_2^c$.

To follow through the logic of the matrix formulation for incorporating the above type of response function and stepped demand functions into the model, first suppose that the supply price is P_1^c and thus that it is profitable to produce some amount of the product. With a positive price of nitrogen (V_n^c), the maximum per acre corn yield, given by the vector Y^c in the production activities set, will not be obtained if the optimal nitrogen rate is applied. Rather, at a price ratio of P_1^c/V_n^c, only $Y_1\%$ (from table 2) of the maximum per acre yield will be obtained. This is reflected in the model by the first sell corn activity, taking for each unit sold an amount $(100/Y_1)$ of the maximum per acre yield (row 2). To reflect the stepped nature of the demand function, the amount of the product that can be sold at P_1^c is constrained by the corn demand step row to be less than or equal to Q_1^c. The optimal nitrogen level is at a price ratio of P_1^c/V_n^c in n_1 pounds per unit of the product (from column 3, table 2). The total nitrogen requirement will thus be n_1 times the quantity sold at P_1^c. The cell of the matrix given by the corn nitrogen needs row (row 16) and the first sell corn column (column 14) will thus give the total quantity of nitrogen required.

[a] The index increases as one goes down the column of figures.

Supposing that the maximum quantity that can be sold at P_1^f (Q_1^f) is sold, consider selling an additional quantity at the next highest price (P_2^f). Since P_2^f should be used in calculating the optimal nitrogen rate on the intramarginal production as well as the marginal production, the per acre yield and nitrogen rate used in producing the quantity sold at P_1^f must be adjusted if any production is sold at P_2^f. In the model this adjustment is affected by the addition of a correction activity (column 6) that must enter the basis if the second sell corn activity enters. Suppose now that P_2^f enters the solution at its limit of $(Q_2^f - Q_1^f)$. The constraint on row 26 will force the correction activity given by column 6 to enter the solution at a level of Q_1^f. This activity does not incur any direct cost; however, it does reduce the amount of the maximum production that can be sold by $Q_1^f[(100/Y_2) - (100/Y_1)]$. Also, it corrects the optimal amount of nitrogen by an amount equal to $Q_1^f(n_2 - n_1)$. If both P_1^f and P_2^f are at their limits, only Y_2% of the maximum possible production will be sold. This production will require n_2 pounds of nitrogen per unit of corn.

If P_1^f enters the solution at its limit, and P_2^f enters at a level less than its limit, the model will give a linear interpolation for yield between Y_1 and Y_2 and a linear interpolation for the nitrogen level between n_1 and n_2 pounds per unit of the product.

There are seventy-eight additional steps on the corn demand function that are not shown in table 1. These additional steps function in the same way as the second step.[3]

Since some harvest costs are proportional to yield, a correct corn harvest cost activity (column 7) is inserted into the model to reduce harvest costs by an amount equal to the per bushel harvest costs (HC) times the difference in the maximum production and the actual production. Similarly, column 8 in table 1 corrects labor requirements that are proportional to yield as well as the phosphorous and potassium fertilization rates for the difference in the maximum production and the actual production.

Additional activities are included in the model to: (*a*) subtract from corn nitrogen needs the amount of nitrogen added by legumes in rotation with corn; (*b*) purchase the required amount of inorganic nitrogen fertilizer for the crops; (*c*) purchase labor; (*d*) purchase phosphorous; (*e*) purchase potassium; and (*f*) allow hay to be baled at a cost of $C per ton or to substitute for pasture with the baling cost.

[3] An alternative way of putting response functions into a model of this type is to define a number of subactivities for different fertilization rates (see Taylor 1975b and Onishi). Then the model could choose a linear combination of the various rates as well as a linear combination of other characteristics of the production activities. The disadvantage of this formulation is that it substantially increases the size of the model, while the advantage is that one is not restricted to using a single response function for a crop nor restricted to the special type of function illustrated in table 2. To include subactivities for different fertilization rates in the model reported here, have the same degree of accuracy, and include rates that would be optimal for the same range of price variation would require eighty production subactivities (since there are eighty price levels and eighty steps on the response function) for each activity that has corn in the crop rotation. This would increase the number of columns in the model from 14,821 to 846,357 and decrease the number of rows by two (rows 3 and 4 and columns 6, 7, 8, and 9 would not be needed because these changes could be accounted for directly in the coefficients of the production activities). Consider the relative cost of solving the two formulations. The model in table 1 was solved on an IBM 360-75 computer using an IBM-MPSX package linked to a budget generator, which took thirteen minutes to generate the coefficients on tape in the format required by MPSX and twelve minutes to convert this data to a problem file, which is the internal working file for MPSX. To optimize from scratch takes thirty-five minutes of slow core (500K). The total cost was about $300 per run. Small revisions and the use of an old basis as a starting point in solving the model were less costly. Since the time required to generate the data and convert it to a problem file is, for this problem, about proportional to the number of columns, the model with the eighty subactivities would require 1,427 minutes for these two solution steps rather than twenty-five minutes. The time required to optimize this model would be more than thirty-five minutes, but how much more cannot be calculated a priori. Obviously, the model with eighty subactivities would be prohibitively expensive. Perhaps a less expensive computational strategy would be to cut down on the range of rates and, if the solution was at an extreme, generate new data and resolve until an extreme was no longer encountered.

The basic set of crop budgets used for the study was obtained by updating the prices and input levels in 1970 budgets that were prepared by Worden et al. for the USDA. Since a different regional delineation was used, budgets for LRA's were obtained by weighting with crop acreages the budgets for the USDA regions. These updated budgets for each crop and LRA were then modified to reflect the different yield levels of LCU's, tillage methods, conservation practices, and rotations. Yield adjustment coefficients for LCU's were obtained from unpublished USDA data (USDA 1975). The budgets were also modified to reflect nonyield cost differences for the alternative tillage methods, conservation practices, and rotations. These latter cost adjustment factors were obtained from many sources, including farm management manuals, experiment station bulletins, and unpublished data, but the primary source was the Illinois Cooperative Extension Service. All coefficients are for 1974 technology and price relationships. Specific coefficients will be furnished upon request.

The land acreage base for the model was obtained from the 1967 *National Conservation Needs Inventory* (USDA 1970). The land constraint in the model for a LCU within a LRA was the total of 1967 acreage devoted to the six crops, idle land, and land in conservation programs. The soil loss coefficients in the model were based on the universal soil loss equation (Wischmeier and Smith). The equation is

$$A = RK(LS)CP, \tag{4}$$

where R is rainfall and erosivity index, K is soil-erodibility factor, LS is a topographic factor that represents the combined effects of slope, length, and steepness, C is a cover and management factor, and P is a factor for conservation practices. Values for these factors were obtained from Lee, Wischmeier and Smith, and USDA (1975). For continuous corn under a spring plow system, A ranges from about 3 tons to over 340 tons. Fall plowing increases these figures by an average of about 10%, while chisel plowing reduces them by about one-half. Erosion under straight row cultivation is over 5 times higher than erosion on a terraced field.

Model Results

To provide a base from which to measure the effects of a policy, the model was solved without any pollution policy imposed. This solution, henceforth called the benchmark solution, is summarized in the first column, table 3. The remainder of this table gives the model results for the policies evaluated in this study. These results are discussed in the next five sections. A comparison of the benchmark acreages with actual 1969 acreages is made in table 4 for each LRA.

Herbicide Ban

The impact of herbicide ban on per acre crop yields was based on data from a six-year experiment in which yields with and without herbicides were compared (Slife). Without herbicides, corn yields were reduced by 19%, and soybean yields were reduced by 22%. In line with Slife's data, it was assumed that without herbicides two additional cultivations of corn and soybeans would be made.

As indicated in table 3, the ban reduced consumers' surplus by over $3.5 billion but increased producers' surplus (the economic rent to land) by about $1.8 billion. This policy also reduced the fertilizer load in the environment but increased by 13% the insecticide load in the environment. The insecticide load increased largely because of changes in the location of corn production. Labor used in crop production increased by 7%, largely because of the additional cultivations of corn and soybeans.

Insecticide Ban

Estimates of the effects of per acre crop yields of banning all insecticides are shown in table 5 for each land resource area. For crops and crop rotations not shown in this table, the yield effects are zero. The figures given in table 5 were based on personal communication with entomologists familiar with the Corn Belt (Kogan, Kuhlman) and the corn rootworm study by Taylor (1975a). These estimates apply to the short run. It is not clear what the long-run effects of banning all insecticides would be. On one hand, the elimination of insecticide pressure might permit the insect infestations to increase over the levels experienced in the near past. But on the other hand, the continued use of insecticides might result in an insect population that is resistant to the insecticides and perhaps even more damaging than current strains of insects.

For the insecticide ban, consumers' surplus decreased by $632 million, while producers' surplus increased by $531 million. The price of corn increased by 14¢, but the price of soybeans declined by 4¢. The soybean price drop or the production increase resulted from growing more corn in rotation with soybeans to avoid large insect losses to corn.

Nitrogen Restriction

For the nitrogen policy, it was assumed that the per acre rate would be reduced from a mean rate of about 140 pounds (including nitrogen added in manure and by legumes) to a maximum of either 50 or 100 pounds. It was further assumed that a restriction would apply to any source of nitrates including those added by legumes. Since the precise relationship between nitrogen fertilizer applications and nitrate pollution damages has not been established (Aldrich), there is presently no sound basis for restricting fertilizer use to either level. The 50 and 100 pound levels were chosen to cover the range of possible restrictions.

Table 5. Estimated Average Yield Change from Banning all Insecticides

Region	Rotation			
	Corn after Corn	Corn after Soybeans	Corn after Small Grains	Corn after Hay or Pasture
	%

Indiana and Ohio till plain	−5	0	−2	−6
Central claypan areas; southern Illinois and Indiana thin loess and till plain; Central Mississippi Valley wooded slopes	−2	0	−2	−5

The 100 pound restriction reduced consumers' surplus by $231 million, while the 50 pound restriction reduced it by $3,325 million. Producers' surplus increased by $21 million with the 100 pound restriction and by $2,036 million with the lower restriction. Producers' surplus increased with the restriction primarily because the price and quantity changes to a large extent occurred in the inelastic portion of the demand curve for corn and soybeans. Thus, a nitrogen fertilizer restriction, which would clearly be to the disadvantage of an individual landowner if imposed only on his farm, would be to his advantage if imposed in a large region.

Under the 50 pound restriction, corn acreage increased by 3.5 million acres. But the higher acreage did not compensate for the reduction in per acre yield. Hence, the quantity produced went down by 478 million bushels, and price went up by 62¢ per bushel. Although the restriction gave soybeans a comparative advantage over corn, the increased pressure on the land base for corn production increased the price of soybeans by 56¢ per bushel. The restriction reduced the acreage of corn grown in rotation with soybeans or small grains; hence, insecticide expenditures increased by 11¢.

The average nitrogen load on corn acreage decreased from a benchmark level of 101 pounds per acre to 76 pounds per acre under the 100 pound restriction and to 49 pounds per acre under the 50 pound restriction. The load is below the restriction level because the optimal nitrogen rate on some of the poorer land is below the restriction level and the average is pulled down. The nitrogen load was reported in terms of corn acreage because the other crops do not require substantial addition of nitrogen to the soil. Unfortunately, the impact of this reduced load on the nitrate content of water supplies is an unclear issue at the present time and may continue to be so in the near future because of the complexity of the nitrogen cycle (Aldrich). Until this information becomes available, it will not be possible to compute the social value of damages abated by nitrogen restrictions.

The administrative and enforcement costs associated with a per acre restriction would indeed be very high. Strict enforcement would obviously be unworkable because it would require a twenty-four hour check on all fields. Perhaps an acceptable degree of compliance could be achieved with very stiff penalties for violators combined with random on-the-spot checks. Other nitrogen policies that have lower enforcement costs, such as taxes and markets for pollution rights, have been suggested for this problem (Taylor 1975b); however, these policies would not be expected to be as effective in controlling the intensity of use as a restriction. If the intensity of use, as opposed to total use, is the major factor causing unacceptable nitrate levels in water, then the per acre restriction may be the best alternative. In fact, this was the only policy mentioned in the Illinois Pollution Control Board's proposed plant nutrient regulations.

Erosion Controls

The estimated effects of alternative erosion control policies are shown in table 3. Accepting Harberger's applied welfare economics postulate that producers' and consumers' surpluses should be added to arrive at the net social cost of an action, we find the relationships between gross soil loss and net social cost (excluding administrative costs and environmental values) that are shown in figure 1. As expected, the socially least costly method of achieving a specified level of soil loss is a tax. The terracing subsidies are substantially more costly than the other control methods considered; however, a terracing cost sharing policy rather than the policy that paid the same per acre amount (irrespective of actual costs of terraces) would have a lower social cost.

A per acre soil loss restriction is only slightly less efficient than the tax policy for reducing soil loss from 595 million tons to about 400 million tons. For achieving a soil loss level of about 337 million tons, a ban on straight row cultivation (i.e., require contouring or contouring and terracing) is only slightly more costly than a tax policy and less costly than a per acre restriction.

In table 3 there are substantial equity differences between the types of erosion control policies. Under the per acre restriction, landowners gain and consumers lose, while the opposite holds for a tax policy. To achieve a soil loss level of about 330 million tons costs $108 million with a tax, $201 million with a per acre restriction, and $133 million with a ban on straight row cultiva-

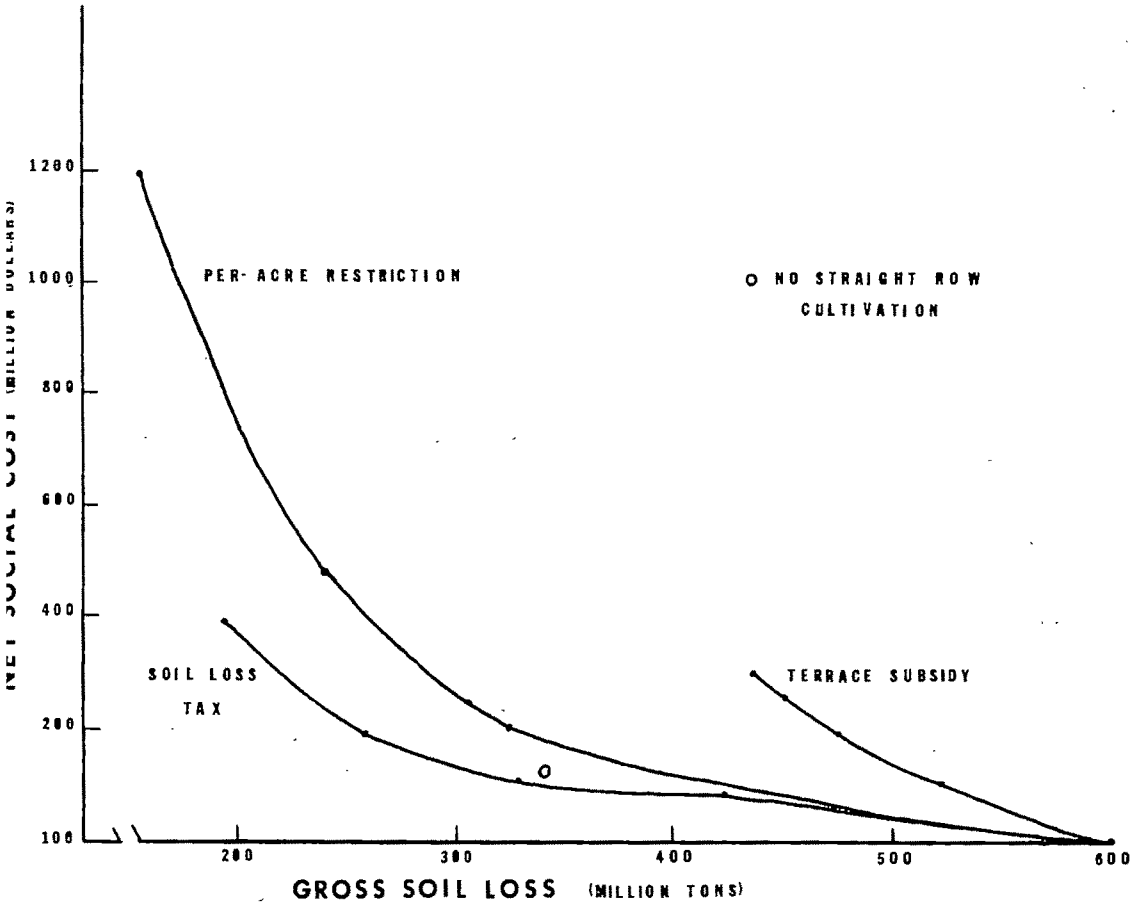

Figure 1. The relationship between net social cost and gross soil loss for the alternative erosion policies

ion. Landowners lose $722 million annually under a tax policy, gain $232 million under a per acre restriction, and lose $145 million with a ban on straight row cultivation. The direction of these land rent effects result primarily from the inelastic demand for corn and soybeans. To achieve a soil loss of 330 million tons, consumers lose $33 million under the per acre restriction, gain $12 million with the ban on straight row cultivation, and gain $286 million under the tax policy. The consumer gain results from the two policies primarily because of relatively lower values for hay and pasture.

Another equity aspect that policy makers might want to consider is the relative impact of the control methods on low income consumers. Because a terracing subsidy policy does not significantly affect prices, the major effect on consumers will be through increased income taxes. Given the progressive nature of the U.S. tax structure, this policy may affect low income consumers much less than a policy such as a per acre restriction, which significantly increases food prices but not taxes. The soil loss tax policy might benefit low income consumers the most because it would lower food prices as well as lowering taxes.

Concluding Remarks

A very large linear programming model of crop production in the Corn Belt was presented. This model incorporated stepped demand functions for corn and soybeans and therefore gives an approximate competitive equilibrium solution for these markets. One advantage of this model over other norma-

tive regional models of crop production (see, e.g., Taylor 1975b, Mayer and Hargrove, Heady et al.) that have been used to analyze pollution policies is that it gives a market equilibrium solution. The other models have either been formulated with constant prices or with the quantity demanded fixed. A second important advantage of the model presented here is that it gives a measure of the change in social welfare resulting from a policy, namely, the change in consumers' plus producers' surplus.

A third advantage of this model formulation is that it incorporates the determination of optimal fertilization rates for corn in a computationally more efficient way than has been done in other models. The increased computational efficiency of this formulation allows much more detail to be added either with respect to the number of fertilization rates allowed or with respect to other input levels.

This model was used to estimate the effects of various controls on nonpoint agricultural sources of pollution. Extreme controls of banning all herbicides, banning all insecticides, and limiting nitrogen fertilizer use were evaluated to illustrate the consequences that may result if the 1985 goal of zero pollution is strictly interpreted. These runs also show the importance of these chemical inputs to agriculture when price effects and regional shifts in production are accounted for.

Controls on gross soil erosion, which are more likely to be implemented than severe constraints on the use of most chemicals in agriculture, were also evaluated. As expected, a soil loss tax is the least costly method for achieving soil loss reductions. However, a per acre restriction, perhaps a politically more viable alternative, was found to be only slightly more costly than a tax for achieving up to a 50% reduction in erosion. The terrace subsidy policy considered was substantially less efficient than the other policies, but a policy that paid only the cost of the terraces rather than a flat rate might be much more efficient.

Future research on agricultural nonpoint sources of pollution needs to concentrate on estimating the external costs of pollution and the administrative and enforcement costs of pollution controls. After this information is obtained, a model of the type presented here could be modified to include these costs and give the socially optimal level of pollution. Future research should also concentrate on finding the optimal mix of point and nonpoint pollution.

U.S. Agricultural Production Capacity

Chung J. Yeh, Luther G. Tweeten, and C. Leroy Quance

This study examines production capacity based on measures of farmers' and consumers' behavioral responses to alternative assumed prices. Impacts of inflation on capacity are also examined. A conceptual framework is outlined, analyzed, and applied to alternative scenarios of projected supply-demand conditions to 1985. Results indicated that long-range U.S. farm production capacity is unlikely to be challenged by 1985. Farmers have substantial capacity to respond to challenges posed by unfavorable weather or other disturbances at home and abroad. Because demands are expected to remain less than supply potential, unutilized supply capacity is expected to remain high.

Key words: capacity, demand, feasible, inflation, production, scenarios, supply, unutilized.

Interest in the production potential of U.S. agriculture is shared by nations around the world concerned about possible food shortages and by farmers and consumers in this nation concerned about prices of farm products. Estimates of production capacity can help such parties at home and abroad anticipate future conditions and make decisions before events reach crisis proportions.

A number of studies have addressed issues of production capacity (Brandow; Heady, Faber, and Sonka; USDA 1973). This study, unlike previous ones, examines production capacity based on measures of farmers' and consumers' behavioral responses to alternative assumed prices. The objectives are to present a conceptual framework for analyzing production capacity and to apply this conceptual framework to alternative scenarios of projected supply-demand conditions to 1985. We discuss results only for 1985, but data were generated for each year using the Economic Research Service's (ERS's) National-Interregional Agricultural Projections (NIRAP) System (Quance).

Chung J. Yeh and Leroy Quance are agricultural economists in the National Economic Analysis Division, Economic Research Service, U.S. Department of Agriculture, and Luther G. Tweeten is Regents Professor in the Department of Agricultural Economics, Oklahoma State University, Stillwater.

The authors are indebted to many economists in Economic Research Service for their helpful comments and contributions to this study. Daryll Ray and Milton Ericksen made helpful comments on the review draft of this study. The authors also wish to thank two anonymous reviewers and the editor of this *Journal* for their helpful comments on the earlier draft of this paper. Only the authors are responsible for possible errors and deficiencies. The views expressed in this article are not necessarily those of the Economic Research Service or the U.S. Department of Agriculture.

Defining Production Capacity

In our market-oriented economy, agricultural output is determined by the price system and public policies underlying investment in agricultural research, extension, education, and resource development. Accordingly, production capacity is measured within the context of prices and public policies required to realize that capacity and is directly tied to the supply function relating output to price. Of course, weather also influences output, but this study focuses on those changes in output that arise from decisions of farmers and consumers.

Within a meaningful range of prices, additional output is not unattainable, only uneconomical. The concept of absolute maximum production capacity is rejected in this study in favor of a more operational concept of feasible supply capacity.[1] Feasible supply

[1] Preliminary calculations indicate that the United States has production potential to provide 3,000 calories of food per day for each of the 4 billion men, women, and children in the world. (Current world consumption averages approximately 2,400 calories per day.) Each pound of wheat, corn, or grain sorghum provides just over 2,000 calories; hence, the entire world requires 2.19 trillion pounds of grain or 39.1 billion bushels of corn-equivalent per year. Disregarding problems of spoilage and waste, the entire output requirement would be filled with corn-equivalent yields in the United States as follows: 77.4 bushel yield on 413 million acres comprised of 317 million cropland acres harvested in 1973 and 96 million acres of cropland with high conversion potential, plus 38.7 bushel yield on 57 million acres of potential cropland with medium conver-

capacity is that output at which the supply curve becomes very unresponsive to price because quality land, fertilizers, other conventional inputs, and management are at such limits that additional output comes only at substantial costs (figure 1); that is, huge quantities of resources would have to be diverted from nonfarm uses to farm uses to gain additional output. Feasible supply capacity must be defined somewhat arbitrarily and is determined in this study on the basis of resource availability, the slope of the supply curve, and the magnitude of prices received relative to prices paid by farmers.

Economic texts define excess supply as supply quantity minus demand quantity at any given price. Quance and Tweeten define excess capacity as the volume of farm production capacity diverted from the commercial market by government programs of acreage diversion, stock accumulation, and food aid. In this study, excess supply capacity is defined as projected supply quantity minus demand quantity at a given price.

Excess supply capacity can be divided into two components—demand reserve and supply reserve. If producer prices are held at the equilibrium P_e and consumer prices held at P_i, a quantity $Q_e - Q_d$ of reserves emerges called the demand reserve in figure 1. If consumer prices are held at P_e and producer prices raised to P_i, a quantity $Q_s - Q_e$ of reserves emerges called supply reserve because it arises from supply response. Together, the demand and supply reserves constitute excess supply capacity $Q_s - Q_d$.

Unutilized supply capacity is the difference between feasible supply capacity and quantity supplied at any price P_i, or $Q_f - Q_s$, while reserve capacity is the difference between feasible supply capacity and demand quantity at any given price P_i, or $Q_f - Q_d$, equal to excess supply capacity plus unutilized capacity in figure 1. Feasible supply capacity is achieved only at a very high price. Public and private measures to meet emerging food needs should be very different if the projected quantity demanded at some future date exceeded, rather than fell short of, feasible supply capacity.

Ability to cope with unanticipated shifts in demand and supply depends strongly on the magnitude of the buffer between quantity supplied and demanded at price P_i. If excess supply capacity is maintained consistent with P_i, then an increase in demand from the quantity Q_d to an unanticipated larger quantity Q_s because of unfavorable weather abroad or for other unforeseeable reasons can be met with the current year's reserve supply without an increase in price above P_i. Or, supply can shift unpredictably from the expected quantity Q_s to a lower actual quantity Q_d, and the shock can be absorbed without a price increase above P_i.

Excess supply capacity is a less ready reserve than commodity stocks.[2] Prices set initially at P_e must be raised to P_i to realize excess supply capacity $Q_s - Q_d$. The reserve is more readily available if price is maintained at P_i year after year. This approach, while maintaining a ready reserve, is very costly. Resources are committed at P_i that have higher value in other uses. These resources, or production therefrom, must be diverted from commercial markets either by paying farmers not to produce, by mandatory controls, by accumulating storage stocks, or by other means.

With a price increase from P_e to P_i, less excess supply capacity is generated in the short run than in the long run because consumers depress food purchases less and farmers increase output less. The long-run supply response, with price P_i maintained for a sustained period, is greater because time is

sion potential, plus 19.4 bushel yield on 112 million acres of potential cropland with low conversion potential, all potentials as classified by the Conservation Needs Inventory (Cotner, Skold, and Krause). While this output would not necessarily be the absolute maximum production capacity, some sacrifice would be required by Americans, including diversion of investment from other activities and direct consumption of cereal and vegetables without processing into meat through animals. Our standard of living would fall sharply as resources were diverted from current uses to massive irrigation programs, land clearing, fertilizer production, etc. Very troublesome issues emerge including transportation, storage, disincentives to food producers in other nations, inability of importers to provide payment, etc. Maximum feasible production capacity is unnecessary under conceivable circumstances and is included here only to illustrate one example of maximum production potential, a tangential concept for this paper.

[2] Agricultural production capacity can be conceptualized in ways different from that reported above. This study does not consider capacity in the very short run; thus, commodity storage stock options are not examined. Maximum production capacity as reported earlier is not considered. Changing the form of farm output constitutes another reserve to feed people. Livestock can be slaughtered to meet current food needs, which provides immediate nutrients from meat and frees crops to be used directly for human consumption at the expense of future meat consumption. Although shifting crop output from processing through livestock to direct human consumption has occurred in the past (e.g., margarine replacing butter) and is expected to continue, we foresee no sharp acceleration of this trend in the future. At high food prices, this trend would be speeded in ways not fully accounted for in this study.

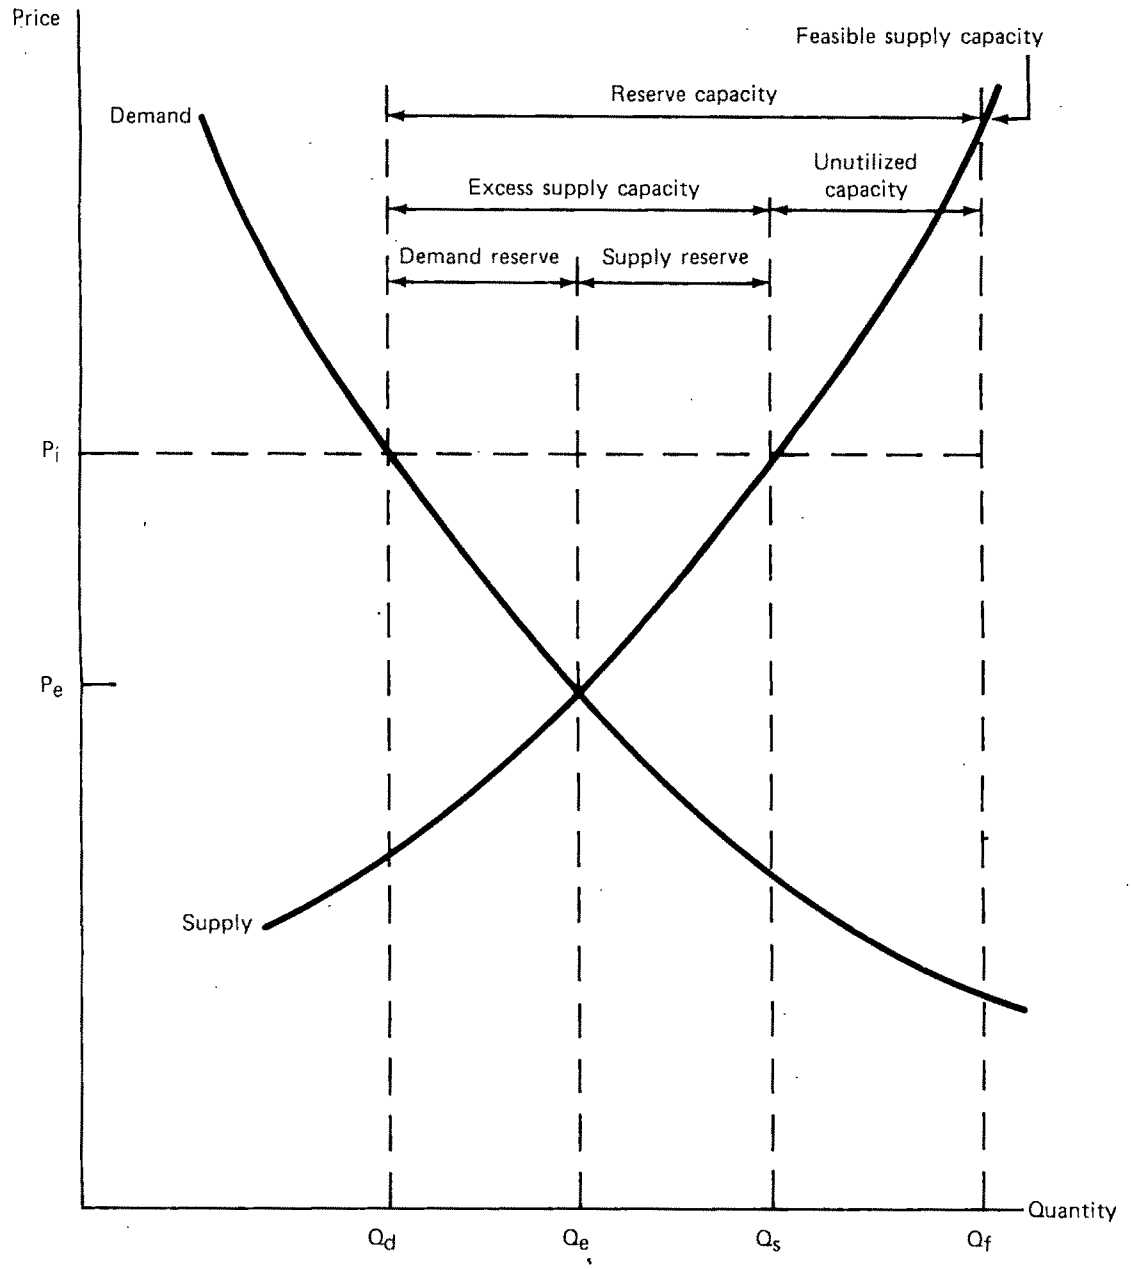

Figure 1. Supply and demand curves illustrating concepts of production capacity

required for farmers to become convinced that additional investment in plant and equipment is justified and for nonfarm firms to increase capacity for supplying production inputs purchased by farmers. The long-run demand response is greater because consumers take time to substitute foods that require fewer resources for foods that require more resources and in other ways adjust diets and substitute nonfood purchases for food purchases. We analyze only "long-run" excess supply capacity in this report, where "long run" is defined as the price P_i maintained from 1975 to 1985.

This study measures output capacity rather than the capacity to provide a number of persons with adequate diets. The capacity to provide more people with adequate diets as farm prices increase is underestimated by our projections, since people substitute foods that require fewer resources to provide an adequate diet (e.g., high lysine corn consumed

directly) for conventional foods if the real prices of food increase markedly.

Parameters and Scenarios

Supply is expressed with two principal parameters: short-run and long-run price elasticities. The NIRAP system performed well in predicting the 1967–74 period with aggregate supply elasticities of 0.2 in the short run (one to two years) and 1.0 in the long run (many years). These results are broadly consistent with past econometric estimates (Tweeten and Quance), adjusted for the increasing short-run elasticity caused by rising proportions of price-responsive inputs such as fertilizer and falling proportions of price-unresponsive inputs such as land and operator and family labor (Yeh).

Demand is also expressed with two principal parameters: short-run and long-run price elasticities. Based on previous econometric studies and the ability to predict historically the 1967–74 period, price elasticities of aggregate demand were selected to be −0.15 in the short run and −0.21 in the long run (Yeh).

Scenarios define the conditions under which supply, demand, and production capacity are projected to the year 1985. The scenarios depict a range of conditions judged most probable. However, the scenarios do not encompass transitory shocks such as intermittent grain purchases for export to the Soviet Union, annual variations in weather, commodity stock adjustments, and other factors that bear heavily on short-run conditions but not on long-run trends. Also, the scenarios do not take into account public policy actions that may be taken to counteract undesirable events, should they appear likely.

Critical scenario components are demand shifters (population, income, and exports) and supply shifters (productivity and inflation).

Supply Shifters

The productivity index is the ratio of aggregate output of the farm production sector to aggregate production inputs. It is assumed that an increase in productivity shifts the supply curve to the right and that additional agricultural research and extension (R&E) outlays raise the amount of farm output available from any given amount of farm production inputs (Cline, McNiel, and Lu).[3]

Alternative levels of R&E expenditures and resulting changes in productivity are considered. The first alternative denoted by T_3 assumes continuation of the observed rate of real growth in R&E during the 1939–72 period—3% per year, a baseline assumption. The second alternative denoted by T_{7+} assumes the continuation of the average rate of real growth in R&E during the 1944–50 period—7% per year—and also includes productivity gains from unprecedented technologies.[4] This is perhaps the upper limit on expected productivity growth through 1985. The estimated annual compounded increase in productivity from T_3 is 1.14%, denoted by $S_{1.14}$, and from T_{7+} is 1.21%, denoted by $S_{1.21}$, from 1975 to 1985 (Cline, McNiel, and Lu). Historical annual average increases in productivity averaged 2.33% in 1950–59, 0.92% in 1960–69, and 1.19% in 1963–72 (USDA 1975a). Although the annual productivity increase measured by the 1965–67 to 1973–75 average was 0.87%, a third alternative, a zero growth rate from 1975 to 1985 denoted by S_0, is considered in the study. Many people believe this may happen or even that there will be a negative productivity growth before 1985.

Other practices such as minimum tillage are not explicitly included in this study but offer potential for greater output from a given dollar volume of production resources (USDA 1975c). Weather also influences the long-run expected productivity trend to the extent that its cycles influence domestic farm production. No provision for these cycles is made in productivity projections herein. Omitting weather conditions is not to deny existence of weather cycles but rather to recognize that these cannot yet be predicted with sufficient reliability to include, in a causal way, in long-run supply projections. Furthermore, this study does not estimate

[3] Effects of increasing R&E are not immediately apparent but are spread over many years. Most occur within thirteen years with the peak effect approximately six years after the year in which extension and research funds are spent (Cline, McNiel, and Lu).

[4] Unprecedented technologies include breakthroughs that are likely to occur at specific times as judged by agricultural scientists but are not included in conventional productivity indices. The three unprecedented technologies are twinning in beef cattle, bioregulators, and photosynthesis enhancement. However, only bioregulators can influence productivity by 1985. Emerging unprecedented technologies are most widely used with greater R&E outlays: hence, their impact is only included with annual real increments on R&E outlays of 7%.

new outlays for public programs to clear, drain, or irrigate additional land but allows for completion of projects authorized and funded.

Inflation as measured by the GNP implicit price deflator has increased historically at a rate similar to that of prices paid by farmers, including interest, taxes, and wage rates. From 1960 to 1969, both indices increased by 24%. From 1972 to 1974, however, prices paid by farmers increased 32%, while general prices increased 18%. The more rapid increase in prices paid by farmers is in part attributed to high energy and fertilizer prices, which carry a larger weight in farm prices than in general prices, and by the interfarm sales component of prices paid by farmers, which increase in price commensurate with the rapid gain in prices received by farmers for crops and livestock. In the future, the rate of gain in prices paid by farmers is expected to return to the historical pattern in relation to the rate of national inflation.

In the empirical analysis, two alternative inflation rates are examined: I_4, the baseline standard case of 4% annual inflation; and I_8, an 8% annual inflation rate in prices paid by farmers. The latter rate is considerably higher than that prior to the 1970s but lower than those farmers experienced in the 1970s.

Inflation shifts the supply to the left at the rate $-BI$, where B is the elasticity of supply and I is the inflation rate of an annual percentage increase in prices paid by farmers for production items including interest, taxes, and wage rates. The vertical axis in figure 1 is illustrated in real rather than in the customary nominal prices. Hence, the impact of inflation on the supply curve is not readily apparent but is included in the analysis. Documentation of the aggregate farm output model of the NIRAP system gives detailed accounts of the impact (Yeh). Influences of inflation in prices paid on prices received by farmers in the empirical analysis are in conformity with the theory outlined elsewhere (Tweeten).

Demand Shifters

U.S. population growth rates are series II and III projections from the Bureau of the Census (U.S. Dep. Commerce). With the population increasing by 0.85% annually from 1970–74 and by 0.70% in 1974 and in the light of falling birth rates, series III projections with an annual growth rate averaging 0.68% (table 1) from 1975–85 were selected as the baseline. Series II projections with annual population growth averaging 0.92% were also included because trends in birth rates can not be accurately anticipated, as evident by past projections.

Table 1. Projected Annual Percentage Increases in Farm Output Demand, 1975–85

Export Growth Rate	Domestic Population Growth	
	II (0.92)[a]	III (0.68)
	High Income[b]	
	(3.2)	(3.3)
3.5	1.73	1.55
4.4	1.88	1.70
6.0	2.15	1.97
	Medium Income	
	(2.5)	(2.7)
3.5	1.66	1.47
4.4	1.81	1.63
6.0	2.08	1.90
	Low Income	
	(1.9)	(2.0)
3.5	1.58	1.40
4.4	1.73	1.55
6.0	2.00	1.82

[a] Roman numerals refer to Bureau of the Census population series, with annual percentage rates in parentheses.
[b] Annual percentage growth in per capita income shown in parentheses below.

The agricultural export growth has been highly volatile in the past and is hazardous to predict. Two rates of future annual agricultural export growth, 3.5% and 4.4% (table 1), were projected by the Foreign Demand and Competition Division (USDA 1976a).

The projections of 3.5% to 4.4% annual growth from 1975 to 1985 appear reasonable in light of present knowledge, but exports could increase at a faster rate, having increased by an average 6% per year from 1967–74, with a large portion of the increase occuring in 1973. While gains of the 1973 magnitude are rare, a faster growth rate alternative of 6% for 1975–85 accounts for any possible continuation of the 1967–74 experience.[5]

[5] These export projections do not measure the need for U.S. farm products abroad.Rather, the estimates reflect projected effective demand for U.S. farm products abroad, which depends, among other things, on ability to pay for U.S. farm

Projected increases in per capita disposable income were computed from working data supplied by Resources for the Future (USDA 1976b). Their annual rates ranging from 3.3% to 2.7% for 1975–85 under population series III appear too high in light of the 2.4% annual gain from 1967–74 and the decline in real income from mid-1973 to mid-1975. Furthermore, higher energy prices may restrain economic growth for an extended period. Consequently, a lower growth rate in income, 2.0%, was included as a third alternative. Comparable high, medium, and low annual rates of growth in real income for population series II were, respectively, 3.2%, 2.5%, and 1.9%. The income elasticity of demand for food and fiber output at the farm level was considered to be 0.14 for 1975–85. Income growth estimates are unique to each population series because income and population interact—lower per capita gains in income are associated with high population growth. However, total national product is greater with higher rates of population growth because population increments are not entirely offset by per capita income loss.

The eighteen possible combinations of the demand shifters (table 1) are too numerous to simulate separately, and only two overall rates of growth in demand are considered. Several combinations of export, income, and population alternatives project the same shift in total demand for farm output. The very highest rates of growth in income seem unlikely to occur. Excluding the highest growth rates in income for 1975–85, the highest annual rate of growth in demand is 2.1% (a combination of an export growth of 6.0%, a population growth of 0.92%, and an income growth of 2.5%). This rate and a standard case or baseline estimate of 1.5% (conforming with the baseline export growth of 3.5%, population growth of 0.68%, and per capita real disposable personal income growth of 2.7%) constitute the two alternatives simulated and are designated as $D_{1.5}$ and $D_{2.1}$. As shown in table 1, these shifts are consistent with several combinations of demand shift components.

Summary of Scenarios

Five scenarios combining different rates of growth in the supply and demand for farm output are analyzed, including a baseline containing the most likely levels of growth to 1985 in supply and demand and four alternatives permitting a limited analysis of the impact on production capacity and especially on reserve capacity of different expected growth rates in technology, inflation, and demand through 1985. In summary, the scenarios are as follows.

(*a*) Baseline ($D_{1.5}\,S_{1.14}\,I_4$)—continue the observed 1939–72 rate of real growth in R&E of 3% per year; 4% annual inflation in prices paid by farmers for nonfarm produced production inputs, including interest, taxes, and wage rates; and a 1.5% annual growth in demand for farm output resulting from various combinations of moderate annual growth in farm exports and in domestic population and income.

(*b*) High technology ($D_{1.5}\,S_{1.21}\,I_4$)—the same supply and demand assumptions as under the baseline except that a higher than expected annual growth in real R&E expenditures—the 7% per year that occurred during the 1944–50 period—and the productivity gains from the unprecedented technologies are included.

(*c*) High inflation ($D_{1.5}\,S_{1.14}\,I_8$)—the same supply and demand assumptions as under the baseline except that a higher than expected annual growth in input price inflation, 8%, is assumed.

(*d*) High demand ($D_{2.1}\,S_{1.14}\,I_4$)—the same supply and demand assumptions as under the baseline except that a higher than expected annual growth in demand for farm output, 2.1%, is assumed, possibly resulting from a combination of higher than expected growth rates in domestic population and income and/or exports.

(*e*) Low technology ($D_{1.5}\,S_0\,I_4$)—the same supply and demand assumptions as under the baseline except that a lower than expected annual shift in supply is included—the 0% per year from 1972 to 1985.

Results

The basic analysis is conducted at the national level with respect to aggregate farm output. The aggregate farm output component of the NIRAP system was used for this purpose (Yeh). In this component, demand is expressed as a function of nominal price and supply as a function of real prices reflecting

products out of funds gained from international exports and aid credits.

the impact of inflation on supply responses. In the simulation, the prices received are determined and expressed as the nominal price. However, in presenting results consistent with the theory outlined earlier, real prices (price ratio) are obtained by deflating externally the prices received by prices paid by farmers for production items, including interest, taxes, and wage rates.

The NIRAP system also includes commodity supply-demand and regional farm commodity production, crop yield, and land-use detail (Quance). However, only illustrative projections relating to commodity production and land use are summarized here.

Equilibrium outcomes show prices and output under various scenarios if prices and quantities are established by market forces at the intersection of supply and demand in the absence of production controls. No excess supply capacity exists at equilibrium, but the entire unutilized supply exists. The equilibrium results in table 2 (first line for each alternative) show estimated output and unutilized supply if the farming economy follows an unconstrained adjustment path to 1985. Alternatively, real prices (ratio of prices received by farmers for crops and livestock to prices paid by farmers for production items, including interest, taxes, and wage rates) are raised to the indicated levels of 120, 140, and 180 from 1975 to 1985.

In the absence of inflation in prices paid by farmers, the price ratio increases steadily from 106 (1967 = 100) in 1974 to 110 in 1985 as demand increases 1.5% annually, while supply increases 1.14% annually due to technology. Under the baseline scenario, the above gain in prices received is more than

Table 2. Agricultural Output and Reserve Capacity under Alternative Scenarios and Price Ratios, 1985

Scenario and Price Ratio[a]	Prices Received	Output[b]	Reserve Capacity (%)[c]			
			Excess Supply

180	541	172.2	7.7	35.3	43.0	0

[a] Price ratio is the index of prices received by farmers for crops and livestock divided by index of prices paid by farmers for production items, including interest, taxes, and wage rates. The preliminary 1974 value is 106 (1967 = 100).

[b] Preliminary actual value of output in 1974 is 108 (1967 = 100). Output here includes interfarm sales and cannot be compared directly with published output series.

[c] Both excess and unutilized supply are expressed as a percentage of output quantity (1967 = 100) at price ratio P_t.

[d] If feasible supply is believed to be 190.9, then the corresponding unutilized supply capacity will be 71.4, 60.6, 39.2, and 0 for the price ratio of 112, 120, 140, and 180.

offset by the 4% annual inflation in prices paid by farmers, and the price ratio falls slightly from 106 in 1974 to 101 in 1985 (table 2). However, the index of prices received increases from 184 (actual) in 1974 to 264 in 1985. One of the reasons that the real price levels at equilibrium decline under most of the scenarios is that demand is considerably less elastic than the supply——0.15 in the short run and −0.21 in the long run for demand and 0.2 in the short run and 1.0 in the long run for supply. Under such conditions, a 1.5% annual shift in demand is not enough to offset the price impact of a 1.14% annual shift in supply from technology.

Feasible supply capacity is judged to be in full use at a real price ratio of 180 under all scenarios. Under the baseline and high inflation scenarios, the feasible supply capacity output is 190.9% of the 1967 output and increases slightly to 192.6% under the high technology scenario. Feasible supply capacity output is 76.9 (190.9 − 114.0) index points (1967 = 100) above equilibrium output under the baseline, hence unutilized capacity is 67.5% of equilibrium output. This implies that by sustaining the price ratio at 180 from 1975 to 1985, output could be two-thirds larger than the equilibrium quantity demanded and supplied.

Quantity demanded would fall from 114.0% of the 1967 output at equilibrium in 1985 to 97.9% if a price ratio of 180 was sustained from 1975 to 1985.[6] Thus, with a price ratio of 180, the 1985 demand reserve (see figure 1) expressed as a percentage of output would be 100(114.0 − 97.9)/190.9 or 8.4%. The 1985 supply reserve is 100(190.9 − 114.0)/190.9 or 40.3%. Thus, of the 93.0, that is, (190.9 − 97.9), index points of excess supply at the feasible supply capacity with a price ratio of 180, 17.2% is demand reserve and 82.8% is supply reserve, the latter dominating due to supply being considerably more responsive than demand to price, especially as length of run is expanded.

A more rapid positive shift in the supply curve due to greater public R&E expenditures does not significantly affect either output or reserve capacity by 1985 as indicated by comparing the high technology case to the baseline. Although the high technology case is a low cost source of agricultural output as indicated by high rates of return on investment, the output and capacity impact is small because of the long lag between expenditures on research and resulting gains in output.

By 1985, high R&E expenditures will lead to equilibrium output 114.3% of 1967 output, with an unutilized reserve capacity sufficient to increase output by 68.5%, slightly more than under the baseline. Feasible supply capacity increases more than equilibrium output because the greater output associated with high R&E outlays results in a lower price ratio to farmers, which restrains conventional input use.

The negative supply shifter, inflation, has a major impact on equilibrium prices and output, a significant impact on reserve capacity, but no impact on feasible supply capacity. With annual increases in prices paid by farmers of 8%, the 1985 farm output is only 107% of 1967 output, compared to 114% under the baseline assumption of 4% annual inflation. The unfavorable economic incentives to produce caused by a low ratio of prices received to prices paid restrain actual output but do not affect potential output as measured by feasible supply capacity. Thus, reserve capacity is very large with high inflation because equilibrium output is low. Massive increases in prices received by farmers are required to realize feasible supply capacity with high inflation rates. For example, by 1985 a price ratio of 180 with an 8% inflation rate will imply an index of prices received by farmers that is 810% of the 1967 average.

Whether demand expansion is rapid or slow does not influence feasible supply capacity, but it does influence the capacity actually utilized. High demand generates favorable price ratios for farmers, causing output to increase. By 1985, equilibrium output will be 119.8% of 1967 output with demand increasing 2.1% per year. Consequently, both excess supply and unutilized capacity are greater for slow than for rapid gains in demand.

The output and capacity is smaller under the 0% shift in the supply than under the baseline. By 1985, equilibrium output will be 111.4% of the 1967 output, and feasible supply capacity will drop as much as 23% from the baseline.

[6] Although the quantity demanded at above equilibrium price ratios is not shown in table 2, it can be calculated as follows. At a price ratio of 180 under the baseline scenario, excess supply is 48.7% of output and thus quantity demanded is 51.3%. The demand quantity at price ratio 180 is (0.513) (190.0) = 97.9.

The excess supply capacity estimates in this study are annual flows in the long run for prices above equilibrium. With expected outcomes under these prices, farmers again pile up huge reserves unless resources are diverted from production. It is well to keep in mind that time, as well as favorable prices, is required to reach the nonequilibrium, high output levels depicted in table 2.

Commodity Estimates

Using commodity supply-demand components of the NIRAP system, we have generated selected commodity estimates consistent with the aggregate farm output production capacity projections summarized above. Opportunities to substitute commodities in both production and consumption make any commodity disaggregation somewhat arbitrary. Our commodity capacity estimates depend on supply and demand parameters that have performed well in a range of projected equilibrium conditions. Because supply estimates are of greatest interest, only capacity estimates that depend on supply are shown for individual commodities. In setting the aggregate price ratio above equilibrium levels, we assume that the component domestic and export demands increase in equal proportions. The resulting supply capacity quantities and prices are feasible points on commodity supply curves. As with aggregate farm output, supply reserve capacity is zero at equilibrium and greatest at the 180 price ratio where unutilized supply is zero.

The real (1974 dollars) supply price for corn drops below the 1974 corn price in the 1985 equilibrium solution. Prices received by farmers relative to prices paid would have to rise above 120 (1967 = 100) before the corn supply price increases above the 1974 corn price of $2.95 per bushel. According to these baseline estimates, if the 1974 real price of corn was maintained until 1985, corn producers would be willing to supply annually approximately 42% more corn than in 1974 and 9% more than the projected equilibrium demand quantity in 1985.

Equilibrium prices in 1985 for other commodities summarized in table 3 are above 1974 prices. Real prices increase about 47% for beef, veal, and wheat and 10% for soybeans from 1974 to 1985. Market-clearing quantities for 1985 are 2% above 1974 levels for beef and veal, 24% for wheat, and about 30% for corn and soybeans.

The feasible supply capacity for 1985 is projected to be corn, 9.6 billion bushels; wheat, 3.5 billion bushels; soybeans, 2.6 billion bushels; and beef and veal, 38.2 billion pounds. Comparable 1985 capacity projections from the 1973 ERS capacity study are corn, 9.1 billion bushels; wheat, 2.3 billion bushels; soybeans, 2.3 billion bushels; and beef and veal, 35.3 billion pounds (USDA 1973).

The 1973 study made the following general assumptions: (*a*) farm product prices favorable for increased production, (*b*) no restrictions on land use, (*c*) adequate input supplies at relatively favorable prices, and (*d*) normal growing conditions. The current study maintains these general assumptions but utilizes the supply and demand components of the NIRAP system to make the price relationships explicit and to apply the conceptual framework outlined earlier in defining and projecting individual demand reserve, supply reserve, and unutilized supply components of production capacity. Given conceptual differences, the 1973 capacity estimates are reasonably consistent with those in this study except for wheat. According to projections generated in this report and considering the 1974 wheat crop of 1.8 billion bushels and the 1975 crop of 2.14 billion bushels, the 1973 wheat capacity projection to 1985 appears to be conservative.[7]

Land and Fertilizer Supplies

Crop yield and land use estimates for the selected commodities at the national level are summarized in table 3. Relative prices well above estimated equilibrium levels bring into production marginal land with lower yield potential, tending to lower national average crop yields. But higher relative prices also encourage irrigation development, greater use of fertilizer, improved machinery, and other types of yield-increasing management practices.

The cropland base is 472 million acres with

[7] Some of the additional acres planted to wheat would come from grazing lands. Higher commodity prices induce clearing, brush and weed control, fertilization, and other measures to raise grazing output. Furthermore, additional cropland needed even at high product prices is small relative to the 900 million acres of grazing lands. Thus, output of grazing lands is expected to increase with higher price ratios.

Table 3. Selected Results under the Baseline Scenario with Alternative Prices, 1985

Commodity and Price[a]	Price Ratio[b] (1967 = 100)	Million Acres Harvested[c]	Output[d] Quantity (mil.)	Output[d] Percentage of 1974	Supply Reserve[d] (mil.)	Unutilized Supply Capacity[d] (mil.)

[a] Prices are in "real" 1974 dollars per bushel for grain and dollars per hundredweight for beef and veal.
[b] Price ratio is the prices received relative to prices paid by farmers.
[c] The actual yields (bu./acre) in 1973 were 91.2 for corn, 31.7 for wheat, and 27.7 for soybeans. The projected yields (bu./acre) in 1985 for all price levels are 111.3 for corn, 38.7 for wheat, and 31.9 for soybeans.
[d] Quantities are in million bushels for grains and million pounds for beef.
[e] The 1973 actual figures.

about 107 million acres being in cropland pasture and soil improvement uses (table 4). These latter acres are considered unavailable for actual crop production in computing future cropland needs. A recent estimate indicates that there are about 265 million acres of land not classified as cropland but with cropland potential (Cotner, Skold, and Krause). This land has various kinds and degrees of limitations that influence the high to low conversion potential indicated in table 4.

The equilibrium 1985 aggregate farm output could be produced without additional land conversion, and the aggregate price ratio for 1975–85 could increase above 120% of 1967 before any of the conversion potential is needed. At a price ratio of 140 and an output 52% greater than 1967, 54% of the acreage with high conversion potential would be used. At the feasible supply capacity price ratio of 180, 100% of the 95.7 million acres of high conversion potential could be used plus 48% of 27.4 million acres of the medium potential acreage. Much of the high and medium potential land would be available in the short run (one to two years), but a high proportion of this land is grassland in the Plains states that could be used only for wheat and low-yielding feed grains. About 55 million acres of the high and medium potential land requires development, mainly drainage. Public as well as private land development investments, along with overcoming environmental problems, is required. No capacity situation projected in this study requires converting any of the 112 million acres with low potential for conversion to cropland.

Pinstrup-Andersen gives some clues to supply of phosphate and potash. World potash reserves are currently estimated to be 79 billion tons of K_2O of which 10 billion tons are readily available. This compares with world production of 22 million tons of K_2O

Table 4. Land Use and Conversion Potential of Land, Baseline Scenario, under Specific Prices[a]

Land Use and Conversion Potential	1973	1985 Ratio of Prices Received to Prices Paid 101	120	140	180
Aggregate farm output (1967 = 100)	104.8	114.0	131.5	152.2	190.9
Cropland used for crops (mil. acres)					
Cropland harvested	317	286	313	382	453
Summer fallow and idle[b]	36	35	35	35	35
Cropland pasture and soil improvement[b]	107	107	107	107	107
Total	460	428	455	524	595
Available cropland (mil. acres)	472	472	472	472	472
Additional cropland needed (mil. acres)	—	—	—	52	123
Conversion potential required for supply capacity (%)					
High	0	0	0	54	100
Medium	0	0	0	0	48
Low	0	0	0	0	0
Total	0	0	0	20	47

[a] Cropland availability and cropland conversion potential estimates were provided by the Natural Resource Economic Division, ERS (see Cotner, Skold, and Krause; USDA 1975b).
[b] Some of this land has potential use for crops, but in these calculations none was considered available.
[c] Acres of land not classified as "available cropland" are estimated to have conversion potential as follows: 95.7 million, high; 57.0 million, medium; and 111.8 million, low, for a total of 264.5 million acres.

in 1973–74. World phosphate rock reserves are estimated to total 76.1 billion tons, and 16 billion tons are estimated to be recoverable at current costs. He estimated 150 years of available consumption at current real costs. Nitrogen is available from the air, but current processing requires hydrocarbons derived from sources such as natural gas, petroleum, or coal. Although natural gas and petroleum supplies could run short, coal stocks are available for hundreds of years at current consumption rates. The drop in prices of nitrogen and phosphate fertilizers in 1976 as a result of large supplies generated by earlier high prices in 1973–74 suggests greater quantities can be generated by higher prices. Given time and adequate prices, the fertilizer industries seem capable of responding to demands to 1985. In the case of imported phosphate and potash, troublesome issues could emerge regarding availability of supplies in the face of possible international political exigencies.

Conclusions

A set of agricultural projections depict alternative futures based on the conceptual framework outlined here and scenarios differing with respect to levels of major influences on the supply and demand for food and fiber. The results can help anticipate emerging needs and required actions before events reach crisis proportions.

Under a projected supply-demand baseline scenario to 1985, including a 1.5% annual increase in demand, a 1.14% annual increase in supply from technology, and 4% annual input price inflation, the U.S. farm sector could have a feasible supply capacity approximately double the 1967 output and 67% larger than the projected 1985 equilibrium output. Feasible supply capacity (at a ratio of prices received by farmers to prices paid by farmers 80% greater than the 1967 ratio) for selected commodities in 1985 are corn, 9.6 billion bushels; wheat, 3.5 billion bushels; soybeans, 2.6 billion bushels; and beef and veal, 38.2 billion pounds. The feasible supply capacity could require that all of the 95.7 million acres of noncropland with high potential for conversion to cropland and 48% (27.4 million acres) of the medium potential noncropland be used in production, which would require major investments.

Long-range U.S. farm production capacity is unlikely to be challenged by 1985. Farmers have substantial capacity to respond to challenges posed by unfavorable weather or other disturbances at home and abroad. Whether actual output is relatively large or small depends on demands placed on the farming

industry in the future. Because such demands are expected to remain less than supply potential, unutilized supply capacity is expected to remain high in the future.

Farmers have much less ability to respond to needs of more output in the short run than in the long run. For example, maintaining an excess supply capacity in 1985 to fill in that one year shortages of the relative magnitude that occurred in 1973 would require a price ratio maintained at nearly 120% of the 1967 average from 1975 to 1985.

Changes in relative prices and use of conventional resources will have a greater impact on farm output in the next several years than will changes in technology through public research and extension. These latter activities require considerable lag time for their efforts to be felt and have comparatively small impact on farm output because they comprise a small part of all agricultural resources.

Toward an Aggregative Measure of Saving and Capital Finance for U.S. Farm Operator Families

John B. Penson, Jr.

The present economic accounting system for the farm production sector fails to measure the personal saving of sector participants and its allocation between financing farm and nonfarm investments. This paper discusses the conceptualization, estimation, and usefulness of two economic accounts covering 1970–75 that provide this information for farm operator families, the largest group of sector participants. These accounts also identify the portion of annual farm capital accumulation financed by internal versus external funds. Analytical ratios illustrating the substantial amounts of equity capital withdrawn to finance nonfarm investments in recent years are presented.

Key words: capital accumulation, capital finance, personal gross saving, portfolio balance.

A fully integrated system of economic accounts should provide a comprehensive and detailed framework for the systematic recording of stocks and flows. The adequacy of such an accounting system should then be judged by whether it can accurately and completely portray the operation and performance of an economic system and the welfare of its participants. In the past, the system of economic accounts for the U.S. farm production sector has consisted primarily of the income account published in *Farm Income Statistics* and the balance sheet account published in the *Balance Sheet for the Farming Sector* (USDA 1976b, c). The strengths and weaknesses of these accounts should be well known to the readers of this *Journal*. Carlin and Handy, for example, recently reviewed the scope and design of these accounts and the role they play in the present sector economic accounting system. Simunek recently estimated a farm capital flow account that, if added to the present sector economic accounting system, would identify specific sources of change in stocks of farm production capital between successive balance sheets.

John B. Penson, Jr., is an assistant professor in the Department of Agricultural Economics, Texas A&M University.

Technical Article No. 12655 of the Texas Agricultural Experiment Station. The author wishes to acknowledge the helpful suggestions of P. J. Barry, D. A. Lins, and two anonymous reviewers.

Yet the sector economic accounting system continues to lack an account or set of accounts that would provide analysts with information on the gross saving of farm production sector participants and the extent to which they finance their farm and nonfarm investments with internal versus external sources of funds. Without this information, analyses of the changing financial position of farm production sector participants must be viewed as partial and incomplete.

Several accounts designed to fill this information gap have recently been proposed in this *Journal* and elsewhere. Much of the attention has centered around the sources-and-uses-of-funds statement for the farm production sector maintained by the Federal Reserve Board and the alternative sources-and-uses-of-funds statement proposed by Penson, Lins, and Irwin. The latter account sought to broaden the scope and design of the Federal Reserve Board account by including, among other things, revaluations of farm real estate as an internal flow of capital. Unfortunately, Penson, Lins, and Irwin failed to separate those real estate capital flows requiring finance from those that do not such as own-account formation of real estate improvements and land revaluations. Brake and Barry recommended further disaggregation of this account, and the exclusion of those transactions that do not de-

scribe the receipt or expenditure of cash. Melichar proposed a procedure for identifying the uses of funds to purchase farm real estate from discontinuing proprietors. Finally, Simunek estimated a farm capital finance account that, among other things, demonstrated the application of saving by farm production sector participants to finance purchases of farm production capital. Yet each of these flow-of-funds accounts represents only a partial answer to the information gap identified above. None of the previously proposed accounts have provided an overall measure of the annual personal consumption and gross saving by farm production sector participants. The scope of the accounts estimated by Melichar and by Simunek was limited to farm capital finance while the accounts estimated by Penson, Lins, and Irwin and by Brake and Barry did not identify nonfarm investments of farm production sector participants apart from their personal consumption outlays. In addition, the sources and uses of funds of farm operator families in each of these accounts were comingled with those of nonoperator landlords and other farm production sector participants, making it impossible to discern whether farm operator families as a group exhibit consumption, investment, and borrowing behavior different from that of other groups.

The purpose of this paper is to review the concepts behind and discuss the estimation and usefulness of two economic accounts that together would allow analysts to observe the manner in which selected groups of farm production sector participants use their personal gross savings to finance farm and nonfarm investments. The scope of the estimated accounts is limited to a coverage of farm operator families, the largest group of farm production sector participants.[1] Their personal consumption and gross saving are measured in a personal income and outlay account. In addition, their finance of farm real estate purchases and capital accumulated on farms is measured along with their net additions to equity in nonfarm capital via a capital finance account. An attempt is made to allow for the effect on gross saving and capital finance of withdrawals by those farm operator families leaving the farm production sector. Procedures to complete these accounts with presently available data are emphasized. Since specific assumptions and statistical procedures are required for the completion of the accounts, data inadequacies are discussed as they arise.

Personal Income and Outlay Account

Carlin and Handy present a conceptual overview of the scope and design of a sector personal income and outlay account. As they suggest, the usefulness of this account can be enhanced by disaggregating sector participants into selected target groups. For the farm production sector, a set of personal income and outlay accounts should be developed for such groups of sector participants as farm operator families, nonoperator landlords, hired labor families, and nonfarm investors such as limited partners.

One of the more important features of this set of disaggregated personal income and outlay accounts is that they would provide an estimate of the personal gross saving by each group of sector participants. Personal gross saving is determined residually in the account by subtracting personal consumption and personal tax and nontax payments from total personal income. Total personal income for each group of sector participants is determined by adding their wages and salaries, rental income, interest and dividends, social security payments, and other income transfers received to the operating surplus of farm and nonfarm businesses accruing to those sector participants having a proprietary interest. For farm operator families (the target group focused on in this study), total personal income is comprised of their net cash farm income and net additions to farm inventories plus any income received from off-farm employment, nonfarm investments, and government. Their personal outlays consist of purchases of nondurable goods and services, personal tax and nontax payments, and personal gross saving.

Those readers interested more in a discussion of the usefulness of the personal income and outlay account for farm operator families presented in table 1 than the statistical procedures and assumptions necessary to

[1] Farm operator families are chosen as the target group for study in this paper because of their relative number and data availability. Little or no information is available at present to estimate the consumption, gross saving, and nonfarm investments of the remaining target groups.

Table 1. Personal Income and Outlay Account, Farm Operator Families, Current Dollars, 1970–75

Item	1970	1971	1972	1973	1974	1975
	Billion $					
Personal income						
1. Current farm operating surplus of farm operators[a]	16.7	17.5	21.4	36.3	30.3	30.3
2. Off-farm wages and salaries, royalties, dividends and interest, nonfarm business profits and professional income, and social security benefits	17.4	18.8	20.5	23.7	26.4	28.4
Total	34.1	36.3	41.9	60.0	56.7	58.7
Personal outlays						
3. Personal tax and nontax payments	3.0	3.2	3.4	4.4	5.1	5.1
4. Net flow of disposable income withdrawn by discontinuing farm operator families	0.5	0.6	0.6	0.5	0.3	0.5
5. Repair and operation of household capital items	3.0	3.1	3.1	3.3	4.3	4.5
6. Purchases of nondurable goods and services by continuing farm operator families[b]	14.8	15.6	16.7	18.2	22.6	26.0
7. Personal gross saving by continuing farm operator families	12.8	13.8	18.1	33.6	24.4	22.6
Total	34.1	36.3	41.9	60.0	56.7	58.7

[a] Net cash farm income plus net additions to farm inventories of continuing farm operator families.
[b] Includes food, household operations, cash rent of living quarters, household dwelling insurance, other housing expenses, clothing, medical care, automobile insurance, personal care, personal insurance, cash gifts and contributions, education, tobacco and alcoholic beverages, recreation, and miscellaneous expenses. Expenditures for shelter, household furnishings and equipment, and motor vehicles are included instead in the capital finance account.

complete the account may skip the following section. These procedures and assumptions are presented to facilitate reestimation of selected entries for those who favor alternative procedures or assumptions and to underscore the nature of the data and need for more frequent surveys pertaining to these entries.

Estimation of the Account

While each of the entries in the personal income and outlay account presented in table 1 is based upon published data, some are estimated from statistical procedures given by the synthesis of data from several different sources. Several assumptions as to the applicability of the results from special surveys to years not covered by the sample are required. Still other entries reported on a net basis require the consolidation of several data series. The following equations and the variable description given in table 2 document the statistical procedures and sources of data used:

$$(1)\quad FOS_{foft} = GCFY_t + \Delta I_{foft} - GCFOE_t - NR_{nopt} - NFY_{ct},$$

$$(2)\quad OFY_{foft} = ((OFY/N)_{foft})(N_{foft}),$$

$$(3)\quad PY_{foft} = FOS_{foft} + OFY_{foft},$$

$$(4)\quad DPYW_t = \Phi(\Delta N_{foft})(PY_{foft}/N_{foft}),$$

$$(5)\quad PCON_{foft} = r_{oi}\left(\sum_{i=1}^{3} 0.33(PY_{foft-i} - PTAX_{t-i} - DPYW_{t-i})\right),$$

and

$$(6)\quad PGS_{foft} = PY_{foft} - PTAX_t - DPYW_t - ROHCI_t - PCON_{foft}.$$

Personal income of farm operator families from farm production activities shown on line 1 of the account is estimated from equation (1). Line 2 of the account, which reports the income earned by farm operator families from off-farm sources, is given by equation (2). Together, equations (1) and (2) account for the current total personal income of these sector participants.[2]

The personal tax and nontax payments entry (line 3) is published in *Farm Income Statistics*, while repairs and operation of

[2] Net additions to crop and livestock inventories on farms are assumed to be accumulated solely by continuing farm operator families since share rents owed to nonoperator landlords have already been deducted and nonoperator landlord purchases of livestock amounted to less than 2% of total livestock purchases in 1970 according to survey estimates presented by Penson and Williams.

Table 2. Variable Description and Sources of Data

Variable	Variable Description and Data Source
FOS_{foft}	Current farm operating surplus accruing to farm operator families (equation (1))
$GCFY_t$	Current cash receipts from farm marketings, other farm income, and government payments (USDA 1976c, pp. 44–45) minus internal sales of breeding livestock (Penson and Williams)
ΔI_{foft}	Current net additions to crop and livestock inventories (USDA 1976c, p. 45)
$GCFOE_t$	Current gross cash farm operating expenses (USDA 1976c, pp. 48–49) minus breeding livestock purchases (Penson and Williams)
NR_{nopt}	Current net rent to nonoperator landlords including government payments (USDA 1976c, p. 54)
NFY_{ct}	Current corporate net farm income (Melichar, Sayre, and Holderness, table 710.2)
OFY_{foft}	Current off-farm income per farm operator family (equation (2))
$(OFY/N)_{foft}$	Current average off-farm income per farm operator family (USDA 1976c, p. 62)
N_{foft}	Current number of farms (USDA 1976c, p. 38)
$DPYW_t$	Current personal disposable income withdrawn by discontinuing farm operator families (equation (4))
Φ	-1 if ΔN_{foft} is < 0; 0 otherwise
$PCON_{foft}$	Current purchases of selected nondurable goods and services by continuing farm operator families (equation (5))
r_{ot}	Ratio of personal outlays for selected nondurable goods and services in 1973 (USDA 1975a) to expected total personal income of continuing farm operator families (equations (1) and (2)), or 0.54
$PTAX_t$	Current personal tax and nontax payments (USDA 1976c, p. 40)
PGS_{foft}	Current personal gross saving by continuing farm operator families (equation (6))
$ROHCI_t$	Current repair and operation of household dwellings (USDA 1976c, p. 51) and motor vehicles where the latter is given by one minus the fraction allocated to business expenses (USDA 1969, p. 11), or 0.78 and 0.40, times the repair and operation of trucks and autos (USDA 1976c, p. 51) divided by the fraction allocated to business expenses
$PGSFC_{foft}$	Current personal gross saving of continuing farm operator families used to finance farm capital accumulation (equation (7))
$TFCA_{foft}$	Total current farm capital accumulation by continuing farm operator families (equation (14))
CB_{foft}	Current total capital borrowing by continuing farm operator families (equation (8))
APP_{foft}	Current total principal payments on debt outstanding by continuing farm operator families (equation (8))
$REDO_t$	Current year-end farm real estate debt (USDA 1976b, p. 19)
$RFCE_{foft}$	Current retained farm earnings of individual and family-held farm corporation; given by NFY_{ct} minus profits tax accruals and dividends paid (Melichar, Sayre, and Holderness, table 730.3) multiplied by the fraction of total gross corporate farm sales accounted for by individual and family-held farm corporations (Coffman), or 0.71
$TVET_t$	Current value of voluntary and estate real estate transfers (USDA 1976d, p. 24)
r_{nopro}	Fraction of total real estate loan funds borrowed by nonoperator landlords in 1970 (Penson and Williams), or 0.09
r_{do}	Debt outstanding on real estate transferred as a fraction of $TVET_t$ in 1967 (USDA 1968, p. 23), or 0.15
$NREDO_t$	Current year-end non-real estate debt excluding CCC nonrecourse loans (USDA 1976b, p. 17)
r_{nopnd}	Fraction of total non-real estate loan funds borrowed by nonoperator landlords in 1970 (Penson and Williams), or 0.02
$TPMV_{foft}$	Current purchases of machinery and motor vehicles for business and household use minus trade-in value (equation (9))
$BPTK_t$	Current purchases of trucks for business use (USDA 1976c, p. 52)
r_{btk}	Fraction of total purchases of trucks allocated to farm business use (USDA 1969, p. 10), or 0.78
$BPAO_t$	Current purchases of autos for business use (USDA 1976c, p. 52)
r_{bao}	Fraction of total purchases of autos allocated to farm business use (USDA 1969, p. 10), or 0.40
$BPTE_t$	Current purchases of tractors and equipment (USDA 1976c, p. 52)
r_{nopc}	Fraction of total purchases of tractors and equipment bought by nonoperator landlords in 1970 (Penson and Williams), or 0.05
$PRECI_{foft}$	Current purchases of real estate capital improvements by continuing farm operator families (equation (10))
$PRECI_t$	Current purchases of real estate improvements (USDA 1976c, p. 52)
r_{nopr}	Fraction of purchases of real estate improvements by nonoperator landlords (Penson and Williams), or 0.09
$NPRE_{foft}$	Current purchases of farm real estate minus sales by continuing farm operator families (equation (11))
r_{baft}	Current fraction of the value of real estate transfers purchased by continuing farm operator families (USDA 1975b, p. 24)
r_{saft}	Current fraction of real estate sellers who are active farm operators at the time of the sale (USDA 1975b, p. 25)
r_{afr}	Fraction of farm operator families selling real estate who remained active in farming after the sale in 1964 (USDA 1965, p. 31), or 0.25
ΔHHF_{foft}	Current net additions to household furnishings and equipment by continuing farm operator families (equation (12))

Table 2. (Continued)

Variable	Variable Description and Data Source
$(HHF/P)_t$	Current year-end stock of household furnishings and equipment expressed in constant dollars (USDA 1976b, p. 5)
PP_{hft}	Current index of annual average prices paid for household furnishings and equipment (USDA 1976a, p. 460)
ΔCDD_{foft}	Current net additions to currency and demand deposits by continuing farm operator families (equation (13))
CDD_t	Current year-end stock of currency and demand deposits (USDA 1976b, p. 13)
$PGSNFC_{foft}$	Current personal gross saving by continuing farm operator families used to finance nonfarm capital accumulation (equation (15))
$\Delta NMFA_{foft}$	Current net additions to time deposits, U.S. savings bonds, and investment in cooperatives by continuing farm operators (equation (16))
$NMFA_t$	Current year-end stock of time deposits, U.S. savings bonds, and investment in cooperatives (USDA 1976b, p. 13)
$\Delta ONFCA_{foft}$	Current net additions to other nonfarm capital accumulated by continuing farm operator families (equation (17))

household capital items (line 5) reflects the remaining expenses not previously included in $GCFOE_t$ (USDA 1975c). The remaining personal outlay entries in table 1 require specific assumptions and statistical procedures. Line 4, for example, is based in part on the assumption that off-farm income of discontinuing farm operator families is less than fully offset by that of incoming farm operator families by an amount equal to the decline in the number of farms times the average off-farm income earned per family during the year. In addition, this entry assumes that the net cash farm income of discontinuing farm operators who sell to nonfarm proprietors transfering land to nonagricultural uses is also withdrawn.

Line 6 presents an estimate of selected personal outlays for household nondurable goods and services by continuing farm operator families (see table 1, footnote b). Excluded are repairs and operation of household capital items, which are accounted for in line 5, and capital expenditures for household dwellings, household furnishings and equipment, and motor vehicles for household use. The national income accounts treat purchases of consumer durable goods with the exception of dwellings as personal consumption rather than household investment, implicitly assuming that these goods are completely consumed within the year they are purchased (U.S. Dep. Commerce). This study instead advocates including purchases of all household capital goods in the capital finance account where they belong. Equation (5) presents the statistical procedure used to approximate outlays for selected nondurable goods and services by continuing farm operator families. Because of the variable nature of personal disposable income during the 1970s and the timing of crop receipts, outlays for these goods and services are assumed to be given by a fraction of expected rather than actual current personal disposable income, where expected current personal disposable income is given by the average annual flow received during the previous three-year period. Thus, the ratio of outlays for nondurable goods and services, with the exception of those associated with repairs and operation of household capital items, found in a 1973 survey of farm operator families to their expected personal disposable income in 1973 is multiplied by the current expected personal disposable income (USDA 1975a). While this procedure is preferred over those considered for which data are available, annual surveys of personal consumption outlays are clearly necessary to insure the acceptance of this account over time.

The final entry in the account is current personal gross saving by continuing farm operator families (line 7), which is determined residually as shown in equation (6). The reliability of this entry therefore is dependent upon the acceptability of the statistical procedures and assumptions employed above. The level of gross saving by farm operator families for 1973, however, should be reliable due to the presence of survey results for personal consumption (USDA 1975a). While alternative procedures and assumptions modify these estimates somewhat, their impact on personal gross saving is likely relatively minor.

Usefulness of the Account

The information on financial outcomes provided by a personal income and outlay account for selected target groups of farm production sector participants is a necessary input to aggregative analyses of their financial position. The account presented in table 1 allows the analyst, for example, to examine the personal consumption behavior of farm operator families. Furthermore, personal gross saving, when added to the proceeds from capital sales and retained farm earnings of individual and family-held farm corporations, identifies the total sources of internal capital finance available to this target group of sector participants.

Among the more interesting comparisons possible with the information presented in table 1 is the ratio of personal gross saving to personal income of farm operator families adjusted for withdrawals by discontinuing farm operator families. This "saving ratio" rose from approximately 39% in 1970 to a high of 58% in 1973 when income from farm production rose sharply. The saving ratio fell back to the 43% level in 1974 and to 41% in 1975 when prices paid for household nondurable goods and services rose dramatically while personal income fell.

Simunek presented an estimate of saving computed residually in a farm capital finance account whose scope was limited to the finance of farm production capital purchases and net additions to farm inventories, currency, and commercial bank deposits. According to him net saving was $4.7 billion in 1973, while gross saving was $10.7 billion, some 70% below the estimate of personal gross saving by farm operator families reported in table 1.

Simunek states, "New research areas and priorities are established by the capital finance account. For example, the estimate of saving permits identification of consumption behavior of the farm sector via the consumption function" (p. 540). While his statement taken by itself is theoretically correct, its application to his estimate of gross saving would lead to measurement error in econometric studies of consumption behavior of farm production sector participants. This is true for two reasons. First, his estimate of a gross saving of $10.7 billion in 1973 represents only that portion of gross saving that is used to finance farm capital accumulation of $15 billion, ignoring that portion used by sector participants to finance household capital purchases and nonfarm investment. Secondly, this account includes the gross saving of all farm production sector participants used to finance farm capital accumulation rather than the saving and investment of a particular unique group of sector participants such as farm operator families. While both account designs are useful for selected purposes, it is important for the analyst to understand their inherent differences and that the estimate of gross saving given by Simunek does not permit the identification of personal consumption or total gross saving of farm production sector participants.

A major question left unanswered by the personal income and outlay account is how farm operator families allocate their personal gross saving between farm and nonfarm investments. To address this question, an additional account is needed that measures sources and uses of funds on capital account for farm operator families.

Capital Finance Account

The purpose of a capital finance account for farm production sector participants is to report the amount of internal and external sources of funds used to finance the capital they have accumulated on and off farms during the year. Many of the reasons cited earlier for disaggregating the sector personal income and outlay account by selected target groups of sector participants are equally applicable to the sector capital finance account. One would expect farm operator families as a group, for example, to exhibit a different portfolio balancing behavior than other groups such as nonoperator landlords. The estimate of personal gross saving by farm operator families presented in table 1, for example, would be shown as a source of internal finance in a capital finance account for this target group.

Like the sector sources-and-uses-of-funds statement, which is predicated on the convention that total sources equal total uses of funds, the capital finance account requires that total capital accumulation equal total capital finance.[3] Capital accumulated on

[3] The capital finance account is quite similar in design but narrower in scope than the sector sources-and-uses-of-funds

Table 3. Capital Finance Account, Continuing Farm Operator Families, Current Dollars, 1970–75

Item	1970	1971	1972	1973	1974	1975
	Billion $					
Capital accumulation						
Farm capital accumulation						
1. Purchases of machinery and motor vehicles for business and household use minus trade-in value	5.3	5.3	6.2	8.1	8.6	9.2
2. Purchases of capital improvements to farm real estate	2.2	2.3	2.1	2.8	3.8	3.5
3. Purchases of farm real estate minus sales	3.2	4.5	6.5	8.6	7.1	7.4
4. Net additions to household furnishings and equipment	0.2	0.7	1.1	0	0.3	0.3
5. Net additions to farm inventories	0	1.4	0.9	3.4	−1.3	2.9
6. Net additions to currency and demand deposits	0.2	0.2	0.4	0.3	−0.2	0
Total farm capital accumulation	11.1	14.4	17.2	23.2	18.3	23.3

11. Total personal gross saving	12.8	13.8	18.1	33.6	24.4	22.6
Total[a]	15.7	18.9	26.0	44.8	33.7	32.0

[a] Due to a lack of data on external finance of nonfarm capital accumulation, the account is restricted to nonfarm equity capital accumulation and finance.

farms during the year by farm operator families can include purchases of farm real estate, farm production capital goods, farm household capital goods, and net additions to farm inventories and cash balances, while capital accumulated off farms would include stocks and bonds, individual retirement accounts, life insurance reserves, nonfarm real estate, and other forms of nonfarm investments.[4] Total capital finance, on the other hand, would include personal gross saving, the proceeds from the sale of capital by continuing farm operator families, retained farm earnings of individual and family-held farm corporations, and the external funds supplied by lenders, limited partners, and others. To enhance the usefulness of the account, the accumulation and finance of farm production, farm household, and off-farm capital should be separately identified in the account.

Table 3 presents a capital finance account for farm operator families during 1970–75. Because of several data limitations identified in the following section, the estimated account takes on a somewhat different design from that desired. Readers wishing to proceed directly to a discussion of the usefulness of this account may skip the following section.

Estimation of the Account

An attempt to focus specifically on the capital accumulation and finance of farm operator families is seemingly thwarted by the fact that farm capital accumulation and finance of nonoperator landlords is not identified apart from that of farm operator families in the present sector economic accounts (USDA 1976b, c). Fortunately, an estimate of farm capital accumulation and finance by Penson and Williams based on a 1970 national survey does distinguish between these two groups of sector participants. These survey results can be used to focus specifically

(SAUF) statement; that is, the SAUF statement can go beyond the capital finance account to show how business outlays on current account, for example, are financed when information on gross flows of production credit is available from all lender groups. Because these data are not available, financial analyses utilizing sector SAUF statements such as that proposed by Melichar are limited to the financing of financial and nonfinancial transactions on capital account, thereby eliminating any differences in the scope of these estimated SAUF statements and the capital finance account.

[4] Net additions to farm inventories includes crop inventories stored on and off farms.

on farm operator families if the fraction of farm capital accumulation and finance accounted for by nonoperator landlords in 1970 is equally valid for 1971–75. The following equations (variable description presented in table 2) document the statistical procedures and data sources used to estimate selected entries in the capital finance account presented in table 3:

$$(7)\quad TPMV_{foft} = (BPTK_t/r_{btk}) + (BPAO_t/r_{bao}) + BPTE_t - ((BPTK_t + BPAO_t + BPTE_t)(r_{nopc})),$$

$$(8)\quad PRECI_{foft} = (PRECI_t)(1 - r_{nopr}),$$

$$(9)\quad NPRE_{foft} = (TVET_t)(r_{baft}) - (TVET_t)(r_{saft})(r_{afr}),$$

$$(10)\quad \Delta HHF_{foft} = ((HHF/P)_t - (HHF/P)_{t-1} + ((HHF/P)/N_{fof})_{t-1}(\Phi(\Delta N_{foft})))(PP_{hft}),$$

$$(11)\quad \Delta CDD_{foft} = CDD_t - CDD_{t-1} + (CDD/N_{fof})_{t-1}(\Phi(\Delta N_{foft})),$$

$$(12)\quad TFCA_{foft} = (TPMV + PRECI + NPRE + \Delta HHF + \Delta I + \Delta CDD)_{foft},$$

$$(13)\quad \Delta NMFA_{foft} = NMFA_t - NMFA_{t-1} + (NMFA/N_{fof})_{t-1}(\Phi(\Delta N_{foft})),$$

$$(14)\quad \Delta ONFCA_{foft} = TCF_{foft} - TFCA_{foft} - \Delta NMFA_{foft},$$

$$(15)\quad TCF_{foft} = (CB - APP)_{foft} + PGS_{foft} + RFCE_{foft},$$

and

$$(16)\quad (CB - APP)_{foft} = (\Delta REDO_t + (TVET_t)(r_{do})(1 - r_{afr}))(1 - r_{noprd}) + (\Delta NREDO_t)\quad (1 - r_{nopnd}) + (NREDO/N_{fof})_{t-1}(\Phi(\Delta N_{foft})).$$

Total capital finance in table 3 consists of net farm capital borrowing, retained farm earnings of individual and family-held farm corporations, and personal gross saving of continuing farm operator families. The procedure for estimating net farm capital borrowing presented in equation (16) reflects an attempt to isolate the net farm capital borrowing of continuing farm operator families. The last term in this equation assumes that discontinuing farm operator families have an amount of non-real estate debt equal to the average non-real estate debt per farm operator family. Some will have no non-real estate debt outstanding at the time of sale, while still others will have substantially more than average.[5]

Omitted from the account is the net inflow of external equity finance supplied by such nonfarm investors as limited partners, which is used to finance capital accumulated on farms by continuing farm operator families. Because of a total absence of data to even approximate this net inflow of funds, increases in this external source of finance to farm operator families are assumed to be exactly offset by nonfarm investor withdrawals. In years of net inflows, the above assumption understates $\Delta ONFCA_{foft}$, while the opposite is true in years of net outflows. One insight to inflows of external equity capital to finance farm capital accumulated by farm operator families is provided by Scofield in a study of agricultural ventures filed with the Securities and Exchange Commission during 1970–71. Scofield reported that more than one-half of these ventures involved limited partnership interests and that the majority of these ventures were to raise capital for either cattle feeding operations or to establish citrus groves, nut orchards, and vineyards. Because uses of funds to establish citrus groves, nut orchards, and vineyards are treated as current expenses in *Farm Income Statistics* and are not identified apart from legitimate current operating expenses, they are not included in total farm capital accumulation in table 3. Thus, external equity capital used to finance these uses of funds would have to be excluded from the capital finance account in any event. Furthermore, not only will a portion of external equity finance of net additions to commercial feedlot inventories be netted out in an annual capital finance ac-

[5] If one instead assumed that discontinuing farm operator families were comprised entirely of older operators of smaller units with zero non-real estate debt at the time of sale, line 2 would decline by a maximum of $0.3 billion in any one year during 1970–74. This, in turn, would increase line 1 and decrease lines 10 and 12 by an equal amount.

count but the external equity capital supplied to general partner-farm operators through these limited partnership interests may represent only a minor portion of their total finance. Dietrich, Martin, and Ljungdahl showed that feed companies, meat packers, retailers, doctors, lawyers, teachers, and other nonfarm custom clients at commercial feedlots accounted for less than 20% of total cattle placements in Texas.[6] Given that net additions to livestock inventories are a relatively small portion of total farm capital accumulation, one can conclude that the lack of data on net inflows of external equity capital may not be as damaging to the creditability of line 12 in table 3 as one might expect. This does not diminish the need for data on this source of external finance to farm operator families.

The proceeds from the sale of farm real estate by continuing farm operator families are assumed to be used to buy other farm real estate so as to avoid capital gains taxes. This assumption, which is similar to that employed by Melichar, is reflected in the capital finance account by reporting farm real estate purchases by continuing farm operator families net of sales (line 3). Thus, the account shows the additional funds necessary to complete these transfers.[7] Purchases of machinery and motor vehicles for business and household use (line 1) are not identified separately in the account since the finance of capital on farms is not identified by the purpose of the loan (USDA 1976b, c); that is, the finance of autos for business use is not separated from the finance of autos for farm household use. In addition, the value of machinery traded in at the time of sale is not identified apart from the purchase price of the new machine (USDA 1976c, p. 52). Finally, a lack of information on gross flows associated with lines 4, 6, and 7 for continuing farm operator families necessitates the use of net flows adjusted for withdrawals by discontinuing farm operator families instead.

Because of a lack of data on the external finance of capital accumulated off farms by continuing farm operator families, the coverage of nonfarm capital accumulation in table 3 is limited to net additions to equity in nonfarm capital. Net additions to time and savings deposits, U.S. savings bonds, and investments in farm cooperatives are estimated from equation (13), while net additions to equity in other forms of nonfarm capital are determined residually as shown in equation (14).

It should be clear from a review of the procedures and assumptions outlined above that more frequent surveys pertaining to selected entries in the account are required to assure its acceptance. The account also represents a first attempt to focus specifically on continuing farm operator families. Further information on the asset holdings and debt outstanding of continuing versus discontinuing farm operator families is needed to refine the estimates from equations (10), (11), (13), and (16). Finally, the strengthening of several published data series such as $PRECI_t$ in the present sector economic accounts directly benefits the capital finance account as well.

Usefulness of the Account

While the design of the capital finance account presented in table 3 differs from that desired due to data limitations, it does provide much of the information essential for aggregative analyses of financial outcomes. Table 4 presents several analytical ratios that identify the relative importance of internal versus external farm capital finance and farm versus nonfarm use of total personal gross saving by continuing farm operator families based on the estimates presented in table 3.

The relative importance of net capital borrowing as a source of farm capital finance has practically doubled during 1970–75. Continuing farm operator families are estimated to have financed 49% of their farm capital accumulation with borrowed funds in 1974 as compared to only 27% in 1970. Because of this, the percentage of farm capital accumulation internally financed declined from 73% in 1970 to 51% in 1974. In 1975 continuing farm operator families increased the portion

[6] Of those ventures to raise capital for beef-breeding herds, most involved direct sales rather than limited partnership interests. Further, these buyers concentrated on small numbers (five to ten) of purebred or exotic breeding cows rather than large commercial cow herds.

[7] The statistical procedure used to estimate the value of real estate sales by continuing farm operator families will overstate this source of funds if the fraction of farm operators remaining active after the sale is less than their fraction of the total value of real estate sold. Because of an absence of data on the number of acres and value per acre of real estate sold by farm operators remaining active after the sale, further adjustment to this procedure is not attempted. Given the relatively small value of the sales estimate, any additional adjustment would likely have little effect on the conclusions drawn from an analysis of the account.

Table 4. Selected Analytical Ratios, Continuing Farm Operator Families, 1970–75

Item	1970	1971	1972	1973	1974	1975
Percentage of farm capital accumulation financed by						
Internal finance[a]	73.0	64.6	54.4	52.8	50.8	60.9
External finance	27.0	35.4	45.6	47.2	49.2	39.1
Total	100.0	100.0	100.0	100.0	100.0	100.0
Percentage of total personal gross saving used to finance						
Farm capital accumulation	63.3	66.4	50.3	35.2	36.5	61.1
Nonfarm equity capital accumulation	36.7	33.6	49.7	64.8	63.5	38.9
Total	100.0	100.0	100.0	100.0	100.0	100.0

[a] Personal gross saving used by continuing farm operator families plus retained farm earnings of individual and family-held farm corporations.

of their farm capital accumulation financed with internal funds to 61%. This comparison by itself does not tell the whole story because it fails to indicate what portion of the total personal gross saving of continuing farm operator families was used to finance nonfarm capital accumulation. Given the assumption that net additions to equity in nonfarm capital by continuing farm operator families are financed entirely from their personal gross saving, clearly these sector participants allocated a declining portion of their total personal gross saving to financing farm capital accumulation during 1970–74. Table 4 shows, for example, that the portion of total personal gross saving used to finance nonfarm capital accumulation rose from 37% in 1970 to a high of 65% in 1973.

To fully assess why continuing farm operator families in general would increase their relative use of borrowed funds to finance farm capital accumulation while at the same time increasing their internal finance of nonfarm capital accumulation is beyond the scope of this study. One can hypothesize that increased variability of farm product prices, coupled with shortages of such production inputs as tractors, the unprecedented levels of personal gross saving, and the dramatic increase in the yields on short-term government securities, would partially explain this shift in portfolios during 1973–74. The reversal of this trend in 1975 coincided with yields on short-term government securities falling sharply and farm product prices stabilizing somewhat.

The results presented in table 4 also suggest the need to disaggregate the capital finance account for this group of sector participants by farm type, size, and tenure groups to explain properly these financial outcomes. The separation of farm operator families associated with livestock farms from those associated with crop farms may help explain the 1974 estimates presented in table 4. Such information should be extremely useful to policy makers who are concerned with the potential impact of their decisions on the financial position of farm production sector participants. For example, at least a part of the current withdrawals by farm operator families to finance nonfarm investments would conceivably be diverted to finance farm capital accumulation in times of emergency or lessened product market uncertainty.

Simunek recently proposed a capital finance account that was limited to the finance of farm production capital accumulation. Capital accumulation in his account is limited to farm production capital expenditures by all groups of sector participants plus net additions to farm inventories, currency, commercial bank deposits, U.S. savings bonds, and investments in cooperatives by farm operator families. The coverage of capital finance is limited to the net farm capital borrowing of all sector participants, gross proceeds from real estate transfer by continuing and discontinuing proprietors, and the residual estimate of saving discussed earlier. The usefulness of this account is limited to a demonstration of the relative importance of capital borrowing in financing farm production capital accumulation. It fails to provide an insight to the complete range of transactions in investment portfolios of farm production sector participants, prohibiting testing of hypotheses regarding the determinants of their portfolio balance.

The theory of portfolio balance suggests that investors simultaneously consider the complete range of portfolio choices (farm and nonfarm) available to them when formulating their desired levels of investment in physical and financial assets (Penson 1972). The capital finance account presented in table 3 attempts to provide this information for continuing farm operator families. The development of additional capital finance accounts for the remaining groups of farm production sector participants would provide the same information as the Simunek account and more. When laid side by side as column vectors in a capital finance matrix, the capital finance accounts for each group of sector participants show the relative contribution to total farm capital accumulation and finance made by each target group. Furthermore, this capital finance matrix provides a better insight to the importance of farm capital accumulation in relation to the total capital accumulated by each group, providing a more meaningful data base for future econometric studies of investment behavior of farm production sector participants.

Summary and Conclusions

This paper proposes the addition of two new accounts to the farm production sector economic accounting system, which together provide needed information on financial outcomes for farm operator families. A personal income and outlay account and capital finance account are estimated for this group of farm production sector participants based upon presently available data to illustrate their potential usefulness. The statistical procedures and data sources used to estimate the accounts are presented to identify existing data deficiencies and facilitate reestimation for those preferring alternative assumptions or procedures. More frequent surveys related to specific entries are suggested to assure the acceptance of these accounts over time and permit econometric analyses of the consumption, investment, and borrowing behavior of farm operator families apart from that of other sector participants.

Estimation of capital finance accounts for each of the remaining groups of sector participants would permit the construction of a sector capital finance matrix. This accounting matrix would show the relative contribution of each target group to total farm capital borrowing and total farm capital accumulation. In addition, it would highlight the relative importance of this source and use of funds to each target group.

It was previously stated that the adequacy of an economic accounting system can be judged by whether it can accurately and fully portray the operation and performance of the economic system and the welfare of its participants. By adopting the economic accounts proposed in this study and seeking ways to more adequately measure selected entries including a more complete treatment of nonfarm capital accumulation and finance of farm operator families, the sector economic accounting system can provide analysts and policy makers with a more complete portrayal of the changing financial position of this group of farm production sector participants.

The Economics of Upgrading Seventy-one Branch Rail Lines in Iowa

C. Phillip Baumel, John J. Miller, and Thomas P. Drinka

Proposed abandonment of branch rail lines in rural areas has stimulated considerable concern over the impact of abandonment on shippers, receivers, and rural communities. The purpose of this paper is to present estimates of the benefits and the costs of upgrading seventy-one branch rail lines. A benefit-cost analysis is used to compare the net benefits with the net costs of upgrading the rail lines. Separate models are utilized to estimate the benefits to grain shippers, fertilizer shippers, and shippers and receivers of all other products from upgrading the branch lines. Benefit-cost ratios are presented for six alternative solutions.

Key words: benefit-cost ratios, grain transportation, rail abandonment, railroads.

Until around 1900, railroads were the dominant mode of transportation in the Midwest. Since then, the development of motor vehicles, highways, airlines, and improvements in waterway transportation have changed the transportation system. As a consequence, railroad officials claim that they now have too many rail lines that are no longer profitable and are sapping financial resources needed to improve the efficiency of the railroad system.

Shippers and communities along branch rail lines view the situation differently. The railroad still is vital, they say, to the survival of farmers, businesses, and communities. But little factual evidence is available to resolve the conflict. Railroads generally cite their poor financial situation as evidence for branch line abandonment. Community leaders cite past traffic as evidence for continued operation of the line.

Public discussions and some studies of the expected impact of rail abandonment implicitly assume that product flows must remain as they have been in the past (Poth). Consider the problem of moving products into or out of Community X located on the branch line in fig. 1. It is 39 miles from Community X to Mainline Junction. Traditional analyses generally assume that should the branch line be abandoned, products must continue to be moved between Community X and the final destination by truck at a considerable increase in cost. Such an analysis ignores other possibly less costly alternatives. For instance, Community X is 5 miles west of the north-south main line serving Community Y. Products leaving Community X could be moved by truck to Community Y and then to the final destination by rail. Road miles would then constitute only a small fraction of the total miles required to move material from Community X to the final destination. Thus, an optimal flow pattern might suggest that it would be less costly to truck 5 miles than to maintain 39 miles of comparatively lightly used rail line.

The optimal flow pattern may be even more dramatic for grain. For instance, a farmer located 4 miles south of Community X could take his grain to the subterminal located on the main line at Community Z by traveling an additional 2 miles rather than going to the elevator at Community X. Since a large portion of the total cost of transporting grain from farm to market is fixed costs that include the costs of owning the tractor, wagon, or truck and the cost of loading and unloading time—regardless of where the grain is moved, the additional time and cost of the extra 2 miles of movement is relatively small compared to the costs of maintaining the 39 miles of lightly used rail lines.

The purpose of this paper is to present

Journal Paper No. J-8476 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa Project No. 2016.

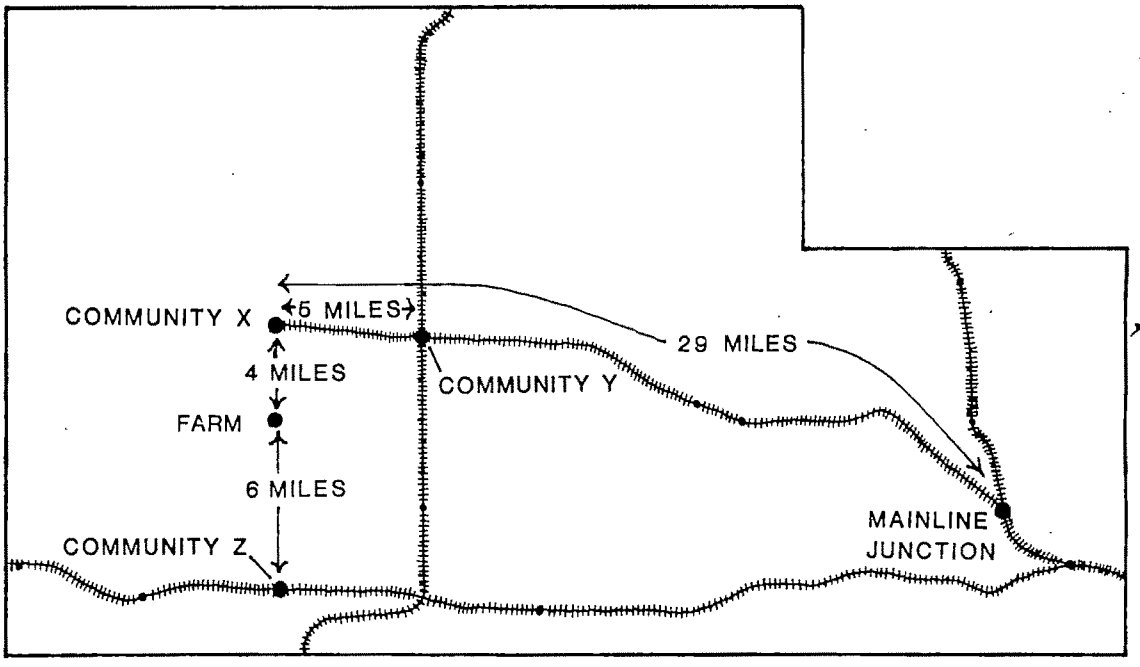

Figure 1. Illustration of possible product flows with a branch line upgraded and alternatively abandoned

estimates of the costs and benefits of upgrading and maintaining branch rail lines in Iowa so that better decisions might be made in developing a transportation system suited to farm, business, and community needs. In this analysis, costs are minimized and/or revenues are maximized under upgrading and abandonment alternatives.

Method of Analysis

Seventy-one branch rail lines are included in the study. These lines represent 32.9% of the total rail line mileage in Iowa. Most of the lines are lighter volume lines in relatively poor condition and may be considered as potential candidates for abandonment. For this analysis, the state is divided into eight "districts," primarily to reduce the number of possible combinations of rail line abandonment.

A benefit-cost analysis is used to evaluate the economics of upgrading the study lines. The benefits from upgrading are defined as the total annual transportation and handling cost saving to grain shippers, fertilizer receivers, and shippers and receivers of other products if the line is upgraded rather than abandoned. The costs of upgrading are defined as the total annualized cost of upgrading the line to 263,000-pound carrying capacity and to Federal Railroad Administration Class II standards—maximum speed of 25 miles per hour—plus the fixed cost of maintaining the line at that level of upgrading. With the declining number of 40-foot, narrow-door boxcars and the increasing use of 100-ton hopper cars, light branch lines with carrying capacities of less than 263,000 pounds are no longer functional for today's rail transportation.

The following benefit-cost ratio, obtained by dividing the total benefits from upgrading the line by the annualized upgrading and fixed maintenance costs, is computed for each of the rail lines:

$$(B/C)_r = \{[GRNC_{r_d-1} - GRNC_{r_d}] + [FC_{r_d} - FC_{r_d-1}] + [OPC_{r_d} - OPC_{r_d-1}]\} \{[(U_r - SU_r) + SA_r][\frac{i(1+i)^n}{(1+i)^n - 1}] - SF_r[\frac{i}{(1+i)^n - 1}] + FMC_r\}^{-1}$$

where r is rail line index, $(r = 1, 2, \ldots, 71)$, B/C is benefit-cost ratio, d is index of dis-

tricts within Iowa, ($d = 1, 2, \ldots, 8$), R is total number of study rail lines or segments of lines evaluated, r_d is index denoting the district rail line network after the rth rail line is theoretically abandoned, designates the rank and number of study lines theoretically abandoned in district d and maps on a one-to-one basis with the rth study line or segment of line in district d, ($r_d = 1, 2, \ldots, R_d$), $GRNC$ is maximum total grain revenue from the sale of grain, net of all transportation costs from farm to market, variable nonfarm storage, and variable handling and annual facility investment costs, FC is minimum total fertilizer transportation and handling costs for transporting the retail fertilizer requirements from the sources of fertilizer supplies to retail locations, OPC is minimum additional transportation and handling costs for products other than grain and fertilizer that originate or terminate on study lines theoretically abandoned, U is total gross upgrading cost, SU is total value of the salvageable material removed during upgrading, SA_r is salvage value foregone if the rth rail line is upgraded rather than abandoned, SF_r is estimated future salvage value of the rth rail line if it is upgraded, FMC is fixed maintenance cost per year, i is interest rate per annum, and n is years of service life.

All study rail lines within a district are assigned a rank (r_d) based upon the ratio defined as the total cars originating and terminating on the rail line from 1 January 1972 to 31 August 1974 divided by the annualized upgrading and fixed maintenance cost of the line. The rail line with the smallest ratio ($r_d = 1$) is the first line to be theoretically abandoned. Then, the line with the next smallest ratio ($r_d = 2$) is considered for abandonment under the assumption that the previously analyzed line has been abandoned. This process continues for all rail lines in each district. When a study line is contained in more than one district, the benefits from each segment of the line are added together to obtain the total benefits of upgrading that line.

In the analysis, product flows for each district are first optimized to maximize the net revenue from grain—corn and soybeans—and to minimize the transportation and handling costs of dry fertilizer and other products, assuming that a given rail line is upgraded. The optimal computer solution identifies the "best" system of transporting these products with the rail line upgraded, given grain prices at all markets and all transportation and handling costs from origin to destination. Then, the flows are reoptimized under the assumed abandonment of the rail line. In effect, the flows are reoptimized using a reduced transportation cost matrix consisting of only truck, truck-barge, truck-rail, and truck-rail-barge cost coefficients for the shippers and receivers on the abandoned line. This second solution identified the "best" system of transporting products with the particular rail line abandoned. The difference between these two computer solutions is the economic benefit of upgrading the rail line. Essentially, the estimated benefits of upgrading are the total annual transportation and handling cost savings to grain shippers, fertilizer receivers, and shippers and receivers of other products if the line is upgraded rather than abandoned.

Grain Model

The nature and scope of the grain distribution system in Iowa where economies of large grain shipments exist suggest a method of analysis based on a transshipment plant-location model. Transshipment plant-location models are used to determine the optimal structure of an industry when transportation costs are incurred from origin to plant and from plant to destination.

Stollsteimer developed a plant-location model to determine the optimal number, size, and location of plants when either transport costs from origins to plants or transport costs from plants to destinations are relevant. Extensions of the Stollsteimer model, incorporating both the transport cost from origins to plants and plants to destinations, were later developed (Baumel et al. 1973, Ladd and Lifferth). The model used in the present analysis is a variation of these extensions and incorporates volume constraints on destinations.

The grain model is based on the following assumptions. The quarterly supply of corn and soybeans at each origin is known. Each grain producer in each district has the option of shipping his grain either to a country elevator or to a subterminal elevator. A country elevator stores and ships grain to a subterminal elevator and/or to "final destinations" including export ports and domestic

processing markets. A subterminal can store and ship to final destinations.

A country elevator may transport grain to a subterminal by truck or to a final destination by truck, truck-barge and, depending upon the availability of rail service, rail or rail-barge. Country elevators cannot utilize multiple-car rail shipments in excess of ten cars because of rail or elevator load-out capacity constraints. Grain received by subterminals may be shipped to final destination in multiple-car rail shipments, truck, rail-barge, or truck-barge. Multiple-car rail shipments from subterminals can be twenty-five cars or more.

Quarterly demand prices for grain at each destination are known and vary by time and commodity. Per unit transportation costs are known and also vary by commodity and time. Variable handling costs vary by commodity, time, and mode of shipment. The quarterly grain prices, net of transportation and variable handling costs, determine where an origin, country elevator, or subterminal will ship the grain.

Some grain distribution facilities, including elevators, subterminals, and rail lines, exist at the beginning of the planning horizon, 1 January 1975. Existing country elevators continue in operation and may be expanded into subterminals, new subterminals may be constructed, and rail lines may be abandoned.

Existing storage facilities of elevators are always used to capacity during the harvest quarter before any elevator expands. Existing grain storage capacity at an elevator, as used in this model, is defined as total storage capacity at the elevator, minus that portion of storage capacity used for working space and back-to-farm shipments of grain. Total construction and/or expansion costs, therefore, vary by location and by size of the existing facility.

Net revenue to producers is maximized subject to the following constraints: (*a*) existing storage facilities of country elevators and subterminals are filled to capacity in the harvest quarter before storage capacity is allowed to expand at any elevator or subterminal, (*b*) Iowa corn and soybean processors receive a quantity of grain equaling 90% to 100% of their projected 1980 processing capacity, and (*c*) the quantity of each commodity shipped from a district each quarter is predetermined.

The objective function of the model is to maximize net revenue to producers within a district under various rail line networks. Net revenue is defined as the income received at final destination minus all handling costs other than previously sunk costs and minus all transportation costs from farm to final destination. The model determined the optimal number of subterminals, the optimal locational pattern of subterminals, and the optimal flow of grain from origins to final destinations, given the rail line network.

The procedure used to determine the maximum total net revenue to producers from the sale of the projected 1980 volume of grain in a district for a given rail line network is divided into three steps. Step 1 selects the minimum-cost routing of each grain from origins to existing country elevators and subterminals in the district such that existing storage facilities are used to their capacity during the harvest quarter. Step 2 selects the routing of each grain from origin to final destination that maximizes the revenue to grain producers net of variable transportation and handling costs, under a given locational pattern of subterminals and a given rail line network in the district, subject to volume constraints on Iowa grain processors. Step 3 selects the number and locational pattern of subterminals that maximize the net revenue to grain producers for a given rail line network in the district. A rigorous description of these algorithms is presented in Baumel, Miller, and Drinka.

Fertilizer Model

The benefits to fertilizer receivers within a district under alternative combinations of branch rail line abandonment are estimated in essentially the same manner as for grain shippers. A modified Stollsteimer transshipment model is used to minimize the cost of transporting the projected 1980 dry fertilizer requirements of retail fertilizer dealers in a district from the supply points to the existing retail locations under various rail line networks. The model determines the optimal number and location of fixed conveyor facilities for transshipping fertilizer and the optimal flows of dry fertilizer from supply points to retailers, given the rail line network, under the following assumptions: (*a*) the demand for fertilizer at each location is fixed and

known; (*b*) there is an infinite supply of fertilizer at specific supply locations; (*c*) phosphorous supplies are located in Florida, potash originates in Saskatoon, Saskatchewan, Canada, urea is manufactured or imported at Donaldsonville, Louisiana, and ammonium nitrate can originate in Clinton, Iowa, or Beatrice, Nebraska; (*d*) fertilizer can be moved from Florida and Louisiana to warehouses and retail locations by rail, rail-truck, rail-barge-rail, or rail-barge-truck or from Houston, Texas, by rail or rail-truck; (*e*) potash and ammonium nitrate can be transported to warehouses or retail locations only by rail, truck, or rail-truck; (*f*) retailers located on an abandoned line can obtain fertilizer by truck from a warehouse or directly from a rail car at a nearby rail line by transferring the fertilizer into a truck through a conveyor; (*g*) potential sites for conveyor facilities include all retail fertilizer locations having at least 900 feet of rail siding; (*h*) all existing fertilizer warehouses are available for use and no new warehouses will be built at sites other than at existing warehouse locations; and (*i*) all existing fertilizer retail sites will remain in operation even with rail abandonment because of the high cost of delivering fertilizer to farms.

Other Products Model

The upgrading benefits derived by shippers and receivers of all other products are also estimated. The "other products" model determines the optimal flow of each commodity group under alternative patterns of rail line abandonment by minimizing the cost of transporting the projected 1980 quantity of each commodity group from locations with rail service to receivers on abandoned lines and from shippers on abandoned lines to locations with rail service. This model is based upon the following assumptions: (*a*) the number and location of other product shippers and receivers located on study lines is given; (*b*) the origin or final destination of each commodity group shipped by rail to each receiver or shipper located on a study line is the same after abandonment of the receiver's or shipper's rail line as before abandonment; (*c*) the quantity of each commodity group shipped by rail to and from each receiver and each shipper located on the study lines is known; (*d*) other products can be moved by truck to receivers and from shippers located on abandoned study lines; (*e*) the quantity of inbound products to receivers on abandoned lines moves by rail from each origin to the nearest location with rail service, and the products are unloaded from the rail car onto a truck and moved to the receiver; likewise, products from shippers are moved to the nearest location with rail service by truck, unloaded from the truck onto a rail car, and moved to the final destination; and (*f*) the rate at which each commodity group is shipped by rail from the location with rail service nearest to the abandoned receiver or shipper is equal to the rate at which each commodity group is currently shipped if his rail line is upgraded. This latter assumption is basically consistent with the real world, where many "other products" move under class or group rates.

Data

All transportation, handling, and facility investment cost data used in the grain, fertilizer, and other product models are in late 1974 price levels. The quantities of grain, fertilizer (Baumel et al. 1974), and other products requiring transportation are projected to 1980. The total amount of projected traffic is substantially larger than the 1972–74 levels. Iowa grain processing demand is also projected to 1980.

In the real world and in the grain model, grain prices at final destinations minus handling and transportation costs determine the quantities of grain shipped to each market. The actual delivered prices for corn and soybeans at each of nineteen major markets for corn or soybeans are obtained for the period April 1974 to March 1975. This set of prices is selected for the following reasons: (*a*) it was the most recent price series available at the time of selection; (*b*) the rail rates used in this study were in effect during most of this period; and (*c*) discussions with grain industry executives indicate that the price relationships among markets in effect during this period are similar to expected 1980 price relationships.

Rail rates are obtained for various sizes of shipments from each Iowa origin to each of the nineteen major markets receiving Iowa grain. These rates were at the Ex Parte 305-A rate levels that were in effect from 20 June

1974 to 27 April 1975. Fertilizer rail rates at the Ex Parte 305-A rate level are obtained from each major fertilizer producing area to each retail and warehouse location in Iowa. Barge rates are taken from barge tariffs in effect from April 1974 to March 1975. These barge rates are adjusted by the average quarterly percent of tariff paid by a medium and a large size shipper located on the Middle Upper Mississippi River.

The costs of trucking grain from farms to elevators and subterminals are estimated for each type of vehicle used by farmers to haul grain. In mid-1974, gasoline and diesel prices delivered to farmers and truckers were 50¢ and 45¢ per gallon, respectively. To specify higher fuel prices for truck shipments than for rail or barge shipments, the delivered fuel prices to farmers and truckers were increased to 60¢ and 50¢ per gallon, respectively. The estimated trucking costs were weighted by the proportion of grain hauled from farms to elevators by each type of vehicle. The weights were obtained by examining 15,180 scale tickets for grain delivered by farmers to a local cooperative during May–June 1974 and October–November 1974. The weighted costs are used to estimate the following aggregate cost functions for hauling grain from farms to elevators and subterminals with an empty return: $C_b = \$0.047 + \$0.0013m$ for harvest time, and $C_b = \$0.058 + \$0.0011m$ for nonharvest time, where C_b is cost per bushel, and m is loaded miles. The constant includes the vehicle ownership costs and the cost of loading and unloading the grain.

The estimated cost function for trucking grain from elevators to subterminals is $C_h = \$0.028 + \$0.002m$, where C_h is cost per hundredweight, and m is loaded miles. Similar trucking cost functions are estimated for fertilizer and for other products moved into and out of locations on branch rail lines.

Variable grain handling costs at elevators, subterminals, and barge loading facilities are taken from published research (Schienbein). Handling costs for fertilizer and other products and the costs of expanding grain and fertilizer receiving, storage, and load-out facilities are estimated from data collected from industry representatives.

The costs of upgrading a line are defined as the net cost of upgrading the line at 1974 price levels annualized over a thirty-five year period (Smith) minus the estimated salvage value of the upgraded line at the end of thirty-five years discounted over a thirty-five year period plus the estimated annual fixed maintenance cost—43% of total maintenance cost (U.S. Interstate Commerce Commission)—of the upgraded rail line plus the salvage value foregone if the line is upgraded, annualized over a thirty-five year period.

Two methods of upgrading are used to estimate upgrading costs. First, used 90-pound rail is utilized to replace existing light rail, and interest is computed at 7% per annum. Since 1 January 1976, 90-pound rail is no longer manufactured. There is insufficient used 90-pound rail available to upgrade all branch lines in Iowa in this manner, but some of the lines could be upgraded that way. Therefore, the alternative method of upgrading used in this study is to replace existing light rail with new continuous-welded 115-pound rail; interest on this expenditure is computed at 10% per annum. The two methods provide a range of upgrading costs with actual costs probably falling somewhere between these two extremes.

One set of benefit-cost ratios is based on single-car rates only. A second set is based on the existing multiple-car structure, which includes single-car, 3- to 10-car, 25-car, and 50-car grain rates, and single-car fertilizer rates from each origin to each retail destination and 10-car rates to large fertilizer warehouses. In addition, a third set of solutions is based on estimated single-car, 3- to 10-car, 25-car, and 50-car rail costs for grain and fertilizer along with estimated costs for 85-car trains scheduled to run continuously between Iowa origins and Gulf of Mexico export elevators (Ingram). Referred to as the "85-car cost structure," this system was based upon estimated costs, since 85-car rates are not presently available in Iowa. A set of six benefit-cost ratios is obtained for each of the lines by using the two upgrading costs and under the three rate or cost structures.

Findings

Of the seventy-one study rail lines evaluated, ten produced a benefit-cost ratio greater than 1.00 under one or more of the six possible solutions. These lines, with their benefit-cost ratios, are listed in table 1. The mileage of the nonstudy lines, plus the mileage of the study lines with benefit-cost ratios ≥ 1.00 under

Table 1. Rail Lines with Benefit-Cost Ratios Greater than 1.00

Line	Single-Car Rates		Multiple-Car Rates		Multiple-Car Costs	
	90-Pound Rail	115-Pound Rail	90-Pound Rail	115-Pound Rail	90-Pound Rail	115-Pound Rail
Estherville to Rake			1.19			
Dows to Forest City	3.15	2.17	3.34	2.30	3.58	2.46
Sibley to Iowa Falls	1.89	1.43	2.25	1.71	2.10	1.59
Moorland to Carroll	1.41	1.12				
Altoona to Pella	1.96	1.47	1.95	1.47	2.06	1.54
Winear to Winterset	11.09	6.87	11.09	6.87	11.19	6.93
Beaman to Gladbrook			2.67	1.75	1.32	
Carroll to Harlan	1.23					
Hancock to Oakland	9.67	6.45	9.46	6.31	9.29	6.21
West Liberty to Burlington	1.65	1.12	1.61	1.09	1.60	1.09

the existing multiple-car rate solution with upgrading with used 90-pound rail, represents 72.1% of the total rail line mileage in Iowa. The lines with benefit-cost ratios < 1.00 represent 27.9% of total rail line mileage in Iowa. This latter set of lines originated and/or terminated only 6.1% of the total number of cars in Iowa from 1 January 1972 to 31 August 1974.

Only four rail lines achieved benefit-cost ratios > 1.00 from large grain transportation and handling cost savings. Five lines achieved benefit-cost ratios > 1.00 from large industrial product transportation and handling savings. The remaining line achieved a benefit-cost ratio > 1.00 primarily because it is in rather good condition, requiring a small investment to upgrade it.

The type of rail rate or cost structure had only minimal impact on the number of lines with benefit-cost ratios ≥ 1.00. Both the single-car rate solution and the existing single- and multiple-car rate solution under the 90-pound level of upgrading had eight lines with benefit-cost ratios ≥ 1.00. The multiple-car cost solution utilizing the 85-car continuous train and using 90-pound rail for upgrading had seven lines with benefit-cost ratios ≥ 1.00. Replacing the existing light rail with new continuous-welded 115-pound rail also had only a minimal impact on the number of rail lines with benefit-cost ratios ≥ 1.00. Each rate or cost solution utilizing 115-pound continuous-welded rail had one less line with a benefit-cost ratio ≥ 1.00 than when used 90-pound rail was utilized. However, the use of new continuous-welded 115-pound rail at 10% interest resulted in a substantial reduction on the level of some of the benefit-cost ratios.

The locations of the lines with benefit-cost ratios ≥ 1.00, $0.75 \leq b - c < 1.00$, and $b - c < 0.75$ are shown in figure 2. Only one line within 150 miles of the Mississippi River has a benefit-cost ratio ≥ 1.00. A large industrial plant relying largely on rail transportation is located on this line. Access to water transportation significantly reduces the benefits of upgrading to grain shippers and fertilizer receivers.

Using the existing multiple-car rail rate structure, an analysis was made of the statewide impact of upgrading eight rail lines rather than all seventy-one rail lines. This analysis is presented in table 2. Net savings accruing to shippers if all the rail lines rather than eight rail lines are upgraded total almost \$4.4 million per year. The savings to grain shippers would be about \$1.5 million per year or approximately one-third of the total benefits. The savings to fertilizer dealers would be about \$1.3 million, while shippers and receivers of other products would save about \$1.6 million per year. The reason for the small savings to grain shippers relative to the large volume of grain transported is that the cost of hauling grain an additional mile is relatively small. Furthermore, even if sixty-three rail lines are abandoned, there would still be a large number of rail lines in Iowa, and since grain originates on a large number of widely dispersed farms, grain flows can be easily altered to minimize the additional travel to a rail line.

The annualized cost to the railroads or shippers or taxpayers—if rail line upgrading is assumed as a public expense—would be about \$20 million for upgrading the additional rail lines and for the salvage value foregone if the lines are abandoned. Thus, the

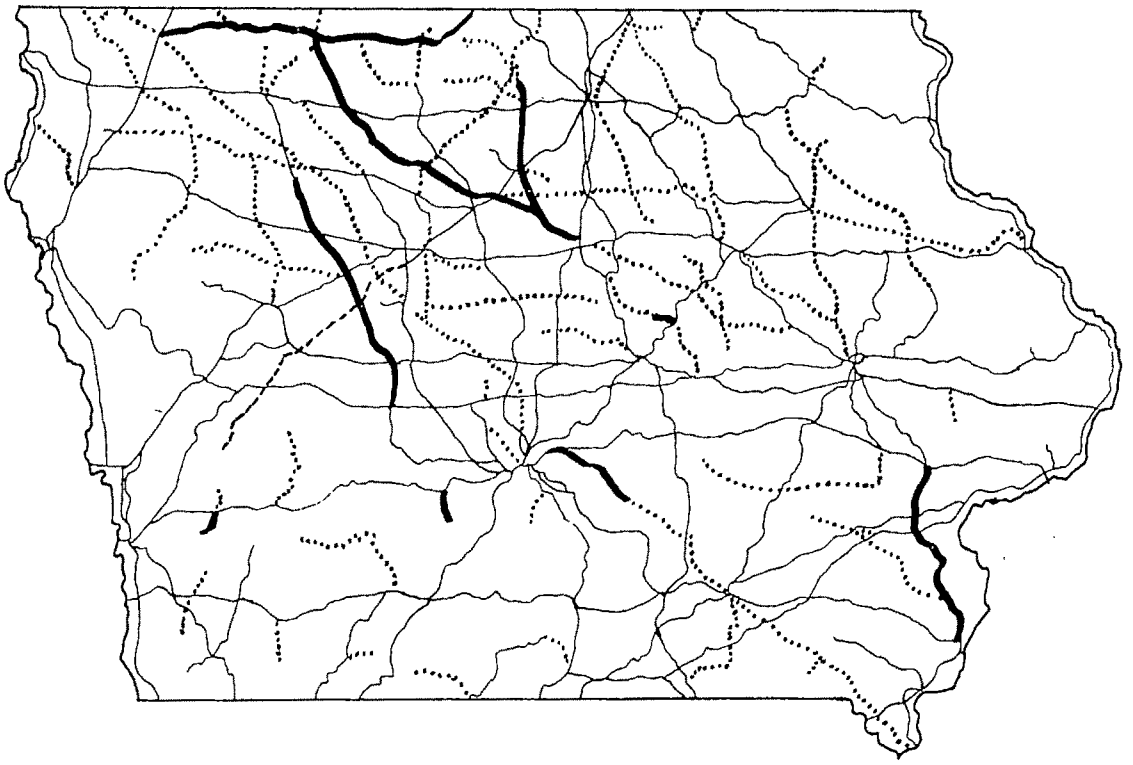

Figure 2. Location of study lines with alternative benefit-cost ratios under the multiple-car rate solution with upgrading to 90-pound rail

—— **Lines not studied**
.... **b − c < 0.75**

—— **b − c ≥ 1.00**

Table 2. Annual Net Benefits to Shippers and the Annual Costs from Upgrading Seventy-one and Eight Rail Lines

	Optimal Multiple-Car Solution for Lines Upgraded with 90-Pound Rail		
	71 Rail Lines	Eight Rail Lines Having a Benefit-Cost Ratio ≥ 1.00	Net Change
	----------1974 $----------		
Benefits to shippers			
Total grain revenue[a]	4,584,439,800	4,582,954,800	1,485,000
Fertilizer transportation and handling costs at fixed conveyor facilities	46,562,500	47,819,000	1,268,500
Other product transportation and handling costs	0	1,605,449	1,605,449
Total benefits			4,358,949
Net annual upgrading and maintenance costs			
Net upgrading and fixed maintenance costs	18,714,956	1,856,987	16,857,969
Salvage from rail lines abandoned	0	3,227,058	3,227,058
Total costs			20,085,025

[a] Revenue is net of transportation, storage, variable handling and drying costs, and additional grain facility investment costs.

average annual benefits to shippers from upgrading the sixty-three rail lines would be 21.7¢ for each annualized dollar invested in upgrading.

If the state was to shift to the transportation system suggested by the optimal multiple-car rate solution, a number of changes would occur. The increased use of larger multiple-car shipments would put more central and western Iowa grain into the export market. Grain shippers in central and western Iowa located on abandoned lines close to Iowa processors would truck grain short distances to Iowa processors rather than ship the grain by rail to Illinois processors or export markets. Shippers in central and western Iowa located on rail lines continuing in operation would ship to Illinois processors and to export markets by rail rather than truck to local grain processors or to river markets as frequently happens today.

Farmers would increasingly haul grain to facilities with the capacity to load multiple-car shipments. In central and western Iowa, at least—even if the branch rail lines are not abandoned—it appears that some of the state's grain flow will abandon some branch lines. Thus, predicting future grain traffic on branch lines on the basis of past flows may not be a meaningful method of analysis.

Rail abandonment is relatively insensitive to rising fuel costs. Assume that a 450-bushel grain truck using diesel fuel costing 50¢ per gallon obtains four miles per gallon and has an empty return. The fuel cost would be 25¢ per loaded mile or 0.056¢ per loaded bushel-mile. The direct effects of a 100% increase in diesel fuel cost would increase the fuel cost to 0.11¢ per loaded bushel-mile.

Conclusions

Basically, at least one of four conditions is necessary for a branch line to produce a benefit-cost ratio ≥ 1.00: (*a*) the line must carry a sizable volume of grain to produce sufficient transportation savings to pay for the upgrading and maintenance costs—and only four of the seventy-one lines analyzed meet this condition in the study; (*b*) the line must have at least one sizable or several smaller nonagricultural shippers to sustain a large volume; (*c*) the line must currently be in rather good condition so that upgrading costs are minimal; or (*d*) the line must be one of the few remaining branch lines in service within an area, thus inheriting additional volume from stations located on nearby abandoned lines.

One reason that so few Iowa rail lines produce a benefit-cost ratio ≥ 1.00 is that there are so many rail lines in the state. In addition, the rail lines generally are in relatively poor condition, requiring large investments to upgrade the lines. Essentially, the additional distance to get to another rail line in Iowa is short. The incremental cost of moving products to or from another line is small compared with the incremental cost of upgrading the rail line. It is estimated that the annual cost to upgrade and maintain all seventy-one study lines examined is about $18.7 million. Most of the rail lines examined in this study serve small rural agriculturally-oriented communities. Similar analyses in states with fewer rail lines than Iowa or in states with a high level of industrial activity might produce results different than those obtained in this study.

Empirical Contributions to Basis Theory: The Case of Citrus Futures

Ronald W. Ward and Frank A. Dasse

A futures basis should reflect the marginal cost of physical product plus a risk premium less a convenience yield. However, unique market characteristics may lead to basis bias not explained by the storage theory. An estimate of the basis model for frozen orange concentrate is used to test the theory of storage and to illustrate anticipatory aspects of the basis not included in storage theory.

Key words: basis, biasness, frozen orange concentrate, futures market.

The performance of futures markets and hence their economic usefulness to industries depends on how well the markets react to industry fundamentals. Market performance is measured in part through an analysis of the basis. Using the basis as an index of performance follows, since basis patterns are the key to commercial utilization of futures contracts. If the basis cannot be explained, then there is reason to question both the market's performance and economic usefulness.

Futures basis has historically been judged by how well it reflects the market fundamentals, i.e., the theory of storage. Yet, the basis may yield discounts or premiums as it reflects anticipation of future events or at least the potential for such events. If this potential is seasonal, then the basis may have a built-in bias. Failure to account for bias generally leads to ineffective hedging and hence a judgment of poor performance. In contrast, if the anticipatory effect is incorporated into the basis model, then the market can be judged recognizing deviations from the theory of storage.

The literature on basis theory is reasonably well developed from a theoretical framework and somewhat less so empirically. In addition, many components to a basis model are unique to the specific contract studied. This uniqueness becomes more evident as new contracts such as frozen concentrated orange juice (FCOJ) are added to the list of commodities and products traded (Ward).

Frozen concentrated orange juice futures is a relatively new contract and represents an innovative concept to the processed food industry. Also, it is an interesting contract to study since many of the unique aspects of a basis can be illustrated. From the citrus industry standpoint, concerns as to how this market has performed have been raised by both growers and processors. Growers and processors represent most of the commercial users of this contract and are most directly affected by basis changes (Dasse).

Given the above considerations, this paper explores empirically those variables contributing to the basis in FCOJ. These efforts are intended to both illustrate basis theory as it applies to a given commodity and to provide empirical reference for judging the economic performance of the orange concentrate contract. The basis model is developed in the first section followed by an estimation of the model for FCOJ. Finally, the last section gives the empirical contributions to the FCOJ basis and their economic interpretation.

Basis Theory

Distant futures exceed the spot price or nearby futures by the cost of storage and transformation, assuming both prices are for similar qualities. However, if nearby prices reflect a current shortage, some convenience yield exists for having at least a minimal

Ronald W. Ward is an associate professor, and Frank A. Dasse is an economist formerly with the Food and Resource Economics Department, University of Florida.

Florida Agricultural Experiment Station Journal Series No. 6209.

stock, and this yield offsets at least part of the carrying cost (Kaldor, Working). If a current surplus exists, the market may pay a risk premium for holding stocks, thus adding to the basis spread. Storage costs, convenience yield, and risk premium have been used to develop the well-known theory of storage (Brennan, Weymar).

Weymar provides an empirical study of the supply of storage for cocoa where the spread between the futures and cash price is related to inventory levels. His model includes both a risk premium and a convenience yield that are related to inventory levels. Brennan's empirical evidence supports much of the early theory of convenience yield with his studies of the supply of storage. He shows that the spread between a futures and spot price can be explained in part by the net marginal outlay for storage. The net marginal outlay is defined as the marginal outlay for physical storage plus a marginal risk-aversion factor minus the marginal convenience yield on stocks. Gray further explores the evidence for a risk premium in spreads and concludes that the risk premium is of little use in partially explaining the spread.[1]

Each of these works adds to the basis theory yet fails to incorporate the uniqueness inherent in each contract market. This omission can distort the empirical results when a specific commodity market is being studied. The distortion in Brennan's model would be reflected in his derivation of the risk and convenience yield components of his model, since they are derived as the residual once the marginal storage cost is subtracted from the basis. In fact, the residual includes both theoretical components as well as contributing factors unique to a particular market.

As indicated above, the FCOJ market is a good example for illustrating the theory of storage in a basis model. A FCOJ basis for a contract t weeks from maturity is defined as[2]

$$(1) \qquad B_t = FP_t - (CP_t + TC_t),$$

where FP is futures prices per pounds of solids of bulk orange concentrate (dollars per pound solids) (Citrus Associates of the N.Y. Cotton Exchange), CP is raw fruit price delivered-in to the processor (dollars per pound solids) (Florida Canners Association), TC is cost of converting raw fruit into bulk concentrate (dollars per pound solids) (Florida Citrus Mutual), and t is weeks remaining in the life of a specific contract. The basis then reflects the cost of storage of bulk concentrate plus any interest on the initial cash outlay for CP and TC. Cost is defined as

$$(2) \qquad M_t = C_t + (e^{rt} - 1)(CP_t + TC_t),$$

where M is total storage and interest cost (dollars per pound solids), C is storage cost for t periods (dollars per pound solids) (Florida Citrus Mutual), r is equivalent weekly interest rate, and $(e^{rt} - 1)$ is an adjustment for calculating interest on the initial cash outlay. Subtracting the outlay from the basis yields the residual (BR_t) to the basis model, i.e., $BR_t = B_t - M_t$. BR then reflects the convenience yield, risk premium, and other variables specifically related to the concentrate market. Figure 1 provides historical weekly values of BR_t.

The FCOJ Basis Model

Basis models cannot be developed without a clear understanding of the chronology of the industry studied. Figure 2 indicates when events occur in the life of a particular FCOJ contract. The season officially begins 1 December, but the first crop estimate by the U.S. Department of Agriculture is released in October. The crop is susceptible to a freeze from December to mid-February, and the late crop is harvested by July.

During the latter months of the season there is considerable speculation about the next year's crop, and this information may be reflected in the contracts extended over these months. Finally, there is a continual need for

[1] The use of the term risk premium in the theory of futures trading has unfortunately taken a dual meaning in the literature. In the theory of storage, the carriers of stocks face an added risk from holding greater inventories and should be compensated for this risk through a risk premium (Cootner; Venkataramanan, p. 22). The theory of speculation includes a concept that hedgers pay to speculators a risk premium for bearing the risk of unanticipated price changes. While these concepts are not at odds they can lead to confusion in the literature (Venkataramanan, p. 52). Venkataramanan provides an extensive review of these concepts in his book, and Dusak gives a recent empirical study of risk premium relating to the theory of speculation.

[2] The basis is calculated with the derived cash price because an equivalent bulk price is not reported. A spot price could be derived using the FOB price and subtracting all cost related to putting the bulk concentrate into consumable packs. However, the FOB price does not respond as readily to weekly market conditions while the delivered-in price (CP) does. Hence, the method used in equation (1) proves to be more sensitive to current market conditions. A general basis model should reflect spatial differences due to delivery points. For FCOJ, however, all delivery points are in Florida, and there is little transportation difference among the delivery points.

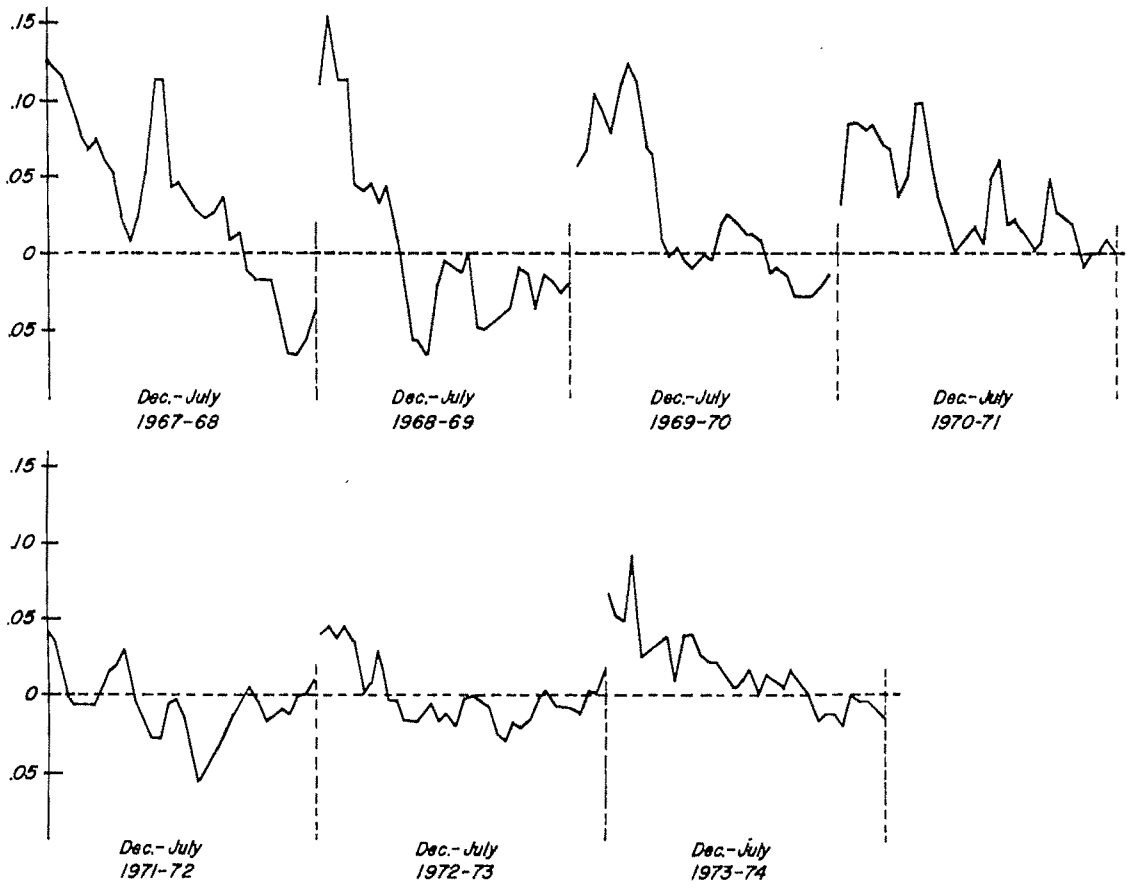

Figure 1. Basis residuals in the July FCOJ contract

storage since much of the fruit is processed into bulk concentrate and later converted to consumable packs (Ward and Dasse).

Recognizing these various events within the crop year, the July contract has been selected for studying the FCOJ basis model. July contracts extend over the complete harvesting period and should reflect a storage cost. Yet this contract is still far enough from the next season to not be greatly influenced by the new season's expected crop.

Six major variables are hypothesized to contribute to the FCOJ basis residual. A measure of risk premium, convenience yield, and market liquidity are general variables expected to be in all basis models, whereas a freeze bias, bias adjustments, and an actual freeze effect may be unique to the FCOJ market (Dasse).

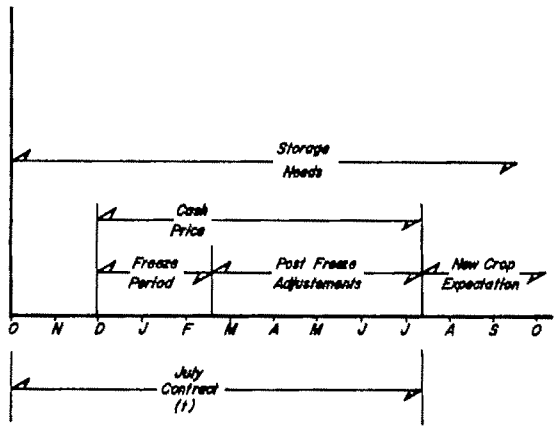

Figure 2. Chronology of citrus harvesting and marketing

Risk Premium

Price risk is inherent in the carrying of FCOJ inventories, and it is reasonable to expect the basis to reflect a risk premium as a facilitator for carrying stocks (Brennan, p. 50). Weymar explicitly notes that commodity holders can be induced to carry additional stocks given

an expectation of a return or risk premium for so doing. For FCOJ the risk from price changes increases as the level of projected stocks increase. If the level of stocks available (SA) projected for the season increases, then the level of price risk commercial traders face also increases. Traders may be induced to hold stocks during periods of high risk if the market pays a risk premium. However, as the contract approaches maturity, the level of risk exposure and hence the risk premium decline to zero.

Empirically, the risk premium (RP) for a contract at t weeks from maturity is defined as

$$RP_t = (SA_t)f(t), \tag{3}$$

where SA is total gallons or frozen concentrated orange juice for the season as estimated monthly by the USDA (millions of gallons), and $f(t)$ is some function of time from maturity (see table 1, footnote b). Changes in the risk premium are reflected in the basis with $\partial BR_t/\partial RP_t > 0$, while $\lim_{t\to 0} BR_t = 0$.

Convenience Yield

Convenience yield (CY) is attributed to being able to take advantage of a rise in demand and price without resorting to a revision of production schedules (Brennan, p. 54). When supplies are short, lack of adequate inventory results in lost sales and operational inefficiencies. Thus, for a firm to draw down inventories below adequate levels, the market must offer to pay for these costs. The market does this by bidding up prices in the near term in relation to distant prices. This allocative mechanism can lead to inverted markets where the convenience yield more than offsets storage cost and the nearby price exceeds the distant contract price.

For FCOJ the yield changes as inventories change. Define S_t as the ratio of inventories (I_t) to the norm ($\bar{I}_t$), then convenience yield changes with S_t such that $\partial CY_t/\partial S_t < 0$, $0 < S < 1$, and $\lim_{s\to 1} CY_t = 0$. When stocks are below the norm there is some positive yield in the basis. Yet as stocks increase up to the norm the yield approaches zero. Furthermore, as the contract nears maturity the market no longer reflects a convenience yield, i.e., $\lim_{t\to 0} CY = 0$, where t represents the weeks from contract maturity.

Using the above arguments with respect to S_t and t, an explicit function representing convenience yield is developed and used in the basis equation

$$CY_t = \begin{cases} \left(\frac{1}{S_t} - 1\right)f(t), & \text{if } 0 < S_t \leq 1, \\ 0, & \text{if } S_t > 1, \end{cases} \tag{4}$$

letting $S_t = I_t/\bar{I}_t$, where I_t is weeks of supplies of inventories on hand measured during t (Florida Canners Association), and $\bar{I}_t$ is average weeks of supplies on hand calculated for each week t and based on an average over the periods from 1958–59 to 1973–74 (Florida Canners Association).

Table 1. Estimates of the FCOJ Basis Residual Model

Equation	Constant	Risk Premium[b]	Convenience Yield	Market Liquidity	Freeze Bias		Freeze	Statistics
					FB	*FBA*		
(8a)[a]	−0.0266	0.3022E-05	−0.0029	0.4538E-04	0.3671	−0.2516	0.0155	$R^2 = 0.58$
	(−4.928)[c]	(1.263)	(−4.135)	(0.083)	(7.179)	(−4.742)	(7.064)	SSE = 0.23
								d = 0.52
(8b)	−0.0071[d]	0.1265E-05	−0.0021	−0.3022E-03	0.3259	−0.2140	0.0110	$R^2 = 0.35$
	(−2.580)	(0.339)	(−1.909)	(−0.955)	(4.147)	(−2.612)	(5.212)	SSE = 0.10
								d = 1.58

[a] Equation (8a) is based on $t^* = 21$ and $\rho = 0.65$. The equations are estimated with seven seasons, 1967–74, beginning the first week of December 1967 ($t = \max t$) and ending with the last trading week of July 1974 ($t = 0$). There are 225 degrees of freedom.

[b] Both risk premium and yield are some function of time into the contract life. Alternative $f(t)$ values (i.e., ln t, t^{-1}, and t) are estimated with the final model selected where $f(t) = t$.

[c] The t-statistics are given in the parenthesis. The variance-covariance matrix shows FB and FBA to be correlated. However, there is no other evidence of potential multicollinearity problems.

[d] The constant terms λ_0 in equation (8) follow from equation (8b), where $\lambda_0 = -0.0071/(1 - 0.65) = -0.0203$. Equation (8b) is estimated under the assumption $\rho = 0.65$.

Market Liquidity

The participation and level of activity by various traders may have a profound effect on the price discovery process. Ward's research indicates that too few speculators in the FCOJ market have a price-distorting effect during the closing contract months. This effect could differ, however, as various periods within the contract life are analyzed. An alternative to the speculative index developed by Ward is to use the ratio of trading volume to the changes in open interest for the contract within a given time period. This alternative is useful when data necessary for calculating a speculative index are not available.

The volume of trading (V) should exceed the absolute changes in open interest $|\Delta OI|$ enough to prevent price distortions from trader entry and exit into the futures market. A liquidity index is defined where both V and $|\Delta OI|$ are measured in contracts traded (Citrus Associates of the N.Y. Cotton Exchange):[3]

$$(5)\quad ML_t = \begin{cases} V_t/|\Delta OI|, & \text{if } |\Delta OI| \geq 1, \\ V_t, & \text{if } |\Delta OI| = 0. \end{cases}$$

The index lies in the range $1 \leq ML_t \leq V_t$ with the lower values suggesting possible liquidity problems. As the level of trading commitments increases, the volume of trading necessary in order to facilitate an orderly market is generally substantially greater than the volume just reflecting the changing open interest. Hence, the index is in the upper ranges in order to prevent possible price distortions.

Freeze Bias

The Florida orange industry is unique in that the production is concentrated geographically and can be severely influenced by a freeze. Empirically, a freeze potential leads to windfall gains to those speculative traders having established long positions in contracts extending over the freeze period. This potential for speculative gains attracts speculators into the FCOJ market, and in turn futures prices are generally bid up relative to the cash market. If the basis declines following the potential freeze period, then it is easy for short commercial traders to develop profitable hedging programs extending over the time of the freeze bias (Ward and Niles).

The actual price response to a freeze is hypothesized to be influenced by expected seasons availability (SA) of stocks. Large inventories lessen the price response if a freeze occurs, and this is reflected in the freeze bias.

There is some period t^* in the life of the contract where the potential for a freeze is over. At the start of each season shown in figure 1 the maximum value of t may differ slightly from one season to the next. Hence, max t is the maximum number of weeks from contract maturity and max $t - t^*$ is the maximum number of weeks the crop is subject to a freeze potential. When $t > t^*$ the market is expected to reflect a freeze bias. As t approaches t^* the bias is expected to decline and remain at zero when $t < t^*$. One alternative variable used to measure this bias is defined as

$$(6)\quad FB_t = \begin{cases} \ln\left(\dfrac{t - t^*}{\max t - t^*} + 1\right), & \text{if } t \geq t^*, \\ 0, & \text{if } t < t^*, \end{cases}$$

where $0 \leq t \leq \max t$ and $t^* < \max t$. As t declines, FB_t changes where $\mathrm{d}(FB_t)/\mathrm{d}t > 0$ and $\mathrm{d}^2(FB_t)/\mathrm{d}t^2 < 0$ for $t > t^*$. In equation (6) $t = \max t$ in the early part of the freeze potential period (see figure 2). When $t = t^*$, FB declines to ln 1 and remains at this value for the life of the contract. The value of t^* is not predetermined but must be established when the basis residual model is estimated.

As indicated earlier, the impact of a freeze potential is expected to be weighted by a measure of the expected seasons availability (SA). If SA is above the norm, then the freeze bias is reduced. Define a freeze bias adjustment (FBA) as

$$(7)\quad FBA_t = (FB_t)(NSA_t),$$

where $NSA = SA_t/\overline{SA}_t$, and $\overline{SA}$ is mean stocks calculated for each week t and based on an average over the 1967–74 seasons.

[3] The definition of ML in equation (5) is appealing in that it immediately suggests how much volume of trading occurs relative to the changes in contract commitments, i.e., if $ML_t = 3$, then trading activities exceed changes in commitments by a factor of three.

Based on equations (3) and (7), *SA* has a two-fold effect in the model. When *SA* is large the market may pay a risk premium for holding stocks. Yet large values of *SA* may dampen the potential windfall gains from a freeze as in equation (7).

Actual Freeze

While the FCOJ contract is hypothesized to reflect a freeze bias during the period $t > t^*$, the futures market may show additional reactions to the actual occurrence of a freeze. In contrast, the cash market may react somewhat slower, leading to upward but temporary adjustments in the basis.

A Florida freeze is generally measured in terms of the degrees below the 28 ° damaging freeze level. If *FZ* is defined as the average degrees below 28 ° during a week, then an increase in *FZ* leads to an increase in *BR*. In subsequent weeks, the cash price also responds to any freeze losses, and then the basis no longer reflects a freeze effect. Hence, in order to adequately explain the concentrate basis model, the unique effect of a freeze on the market must be incorporated into the model.

Empirical Results

The six basis variables have been defined over t with no reference to the data observed for different seasons shown in figure 1. In order to measure the model, each variable should be subscripted by i to denote the k seasons where $1 \leq i \leq k$. The i subscript has been dropped in the presentation for simplicity and should not cause any difficulty with the interpretation of the variables.

Incorporating the properly subscripted variables defined above to explain the basis residual gives

$$(8)\quad BR_{t(i)} = \lambda_0 + \lambda_1 RP_{t(i)} + \lambda_2 CY_{t(i)} + \lambda_3 ML_{t(i)} + \beta_1 FB_{t(i)} + \beta_2 FBA_{t(i)} + \beta_3 FZ_{t(i)} + \mu_{t(i)},$$

recalling from equations (1) and (2) that $BR_{t(i)} = B_{t(i)} - M_{t(i)}$. The λ_j coefficients relate to those theoretical variables common to all commodities, while the β_j's are unique to the FCOJ model. A priori, $\lambda_1 > 0$ since the basis pays a risk premium in accordance with the risk level. In contrast, $\lambda_2 < 0$ since the market reflects the economic value from having a level of stocks available to meet current market needs. The direction of price distortions due to lack of liquidity is not clear a priori, hence $\lambda_3 \gtrless 0$. The freeze bias is measured by positive increases in *BR*, thus, $\beta_1 > 0$. However, the adjustment to the freeze bias reduces the basis bias and $\beta_2 < 0$. Finally, an actual freeze increases the basis as reflected by $\beta_3 > 0$.

Two estimation problems are immediately evident in equation (8). First, the freeze bias variable (equation (6)) includes the constant t^*, which is unknown. Reference to figure 2 shows that generally $18 \leq t^* \leq 26$. Equation (8) is estimated using a maximum likelihood criteria where equation (8) is estimated over the range t^* and then the t^* is selected that gives the minimum sum of squared error (SSE).

Second, all variables are time series measured over k seasons. However, the series is discontinuous in that t does not span the full fifty-two weeks of each season. This gap invalidates the normal correction procedures for autocorrelation problems. The basic problem for this first-order autoregressive model is that the first error in season i is not related to last error in season $i - 1$ since there is a data gap between these two errors. If ρ is the autoregressive coefficient and $t' = \max t - t + 1$, then $\mu_{t'(i)} = \rho\mu_{t'-1(i)} + \epsilon_{t'(i)}$ if $t < \max t$, while $\mu_{1(i)} = \epsilon_{1(i)}$ when $t = \max t$. The autoregressive model is calculated using t' rather than t in order to conform better with standard notation. In the basis model t declines over the season while t' increases. Generalizing,

$$(9)\quad \mu_{t'(i)} = D\rho\mu_{t'-1(i)} + \epsilon_{t'(i)},$$

where $D = 1$ if $t < \max t$ and $D = 0$ if $t = \max t$. Using equation (9), it is relatively easy to show that ρ can be estimated by making the normal data transformation using $D\rho$.[4]

[4] The variance and covariance is calculated where

$$\operatorname{cov}(\mu_{t'(i)}\mu_{t'-s(i)}) = \begin{cases} \rho^s\sigma^2/(1-\rho), & \text{if } s \leq \max t, \\ 0, & \text{otherwise.} \end{cases}$$

Assuming that ρ and σ^2 are homogenous over seasons, then correction for serial correlation is used where the first observation of each seasons is weighted by $(1 - \rho^2)^{1/2}$ and the remaining observations weighted by $y - \rho y_{-1}$.

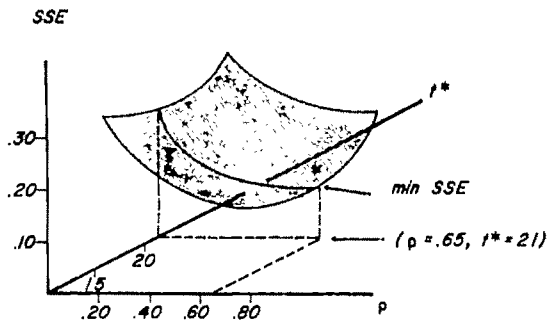

Figure 3. Error sums of squares over values of t^* and ρ

Equation (8) is estimated over the range of t^* and ρ giving the resulting SSE shown in figure 3. As evident in this figure, the freeze period is expected to end when the July contract is twenty-one weeks from maturity (i.e., $t^* = 21$). Similarly, the SSE reaches a minimum at $\rho = 0.65$ with little to no change occurring in the SSE for $\rho > 0.65$. The estimation results for $t^* = 21$ and for both $\rho = 0$ and $\rho = 0.65$ are given in table 1. The t-statistics are in parentheses and the seasonal subscript i is dropped for convenience.[5]

Efforts to establish empirically that the FCOJ market pays a risk premium have failed. There is no significant widening of the basis serving as a risk-rewarding inducement for holding inventories during high risk periods. The actual incidence of risk is a nonobservable variable and must be measured by proxy variables as in equation (3). Therefore, the evidence on risk premium must be interpreted with care since the conclusion can change according to how the actual risk premium variable is measured.

The basis residual model clearly reflects a significant convenience yield as evident in equation (8b) in table 1. The yield changes with both the stock level and the amount of trading time remaining in the contract (see equation (4)). For example, if stocks are 75% of the norm (i.e., $S_t = 0.75$) and if fifteen weeks remain in the contract life, then the contract reflects a yield of approximately 2.4¢ per pound solids. In this example, the basis would be 2.4¢ less than when supplies are normal.

Figure 4 shows various levels of yield over t and S_t. Although the convenience yield is present, it remains relatively small as long as $S_t > 0.75$. When $S_t < 0.75$, the yield increases substantially since

$$(10)\quad \frac{\partial BR_t}{\partial S_t} = \begin{cases} 0.0021t/S_t^2 > 0, & 0 < S_t < 1, \\ 0, & S_t \geq 1. \end{cases}$$

As S_t declines, the convenience yield increases and the basis residual declines and could ultimately result in a negative price spread. In such a case, the basis does not cover the full outlay developed in equation (2). Also, the presence of t in equation (10) further illustrates that the yield cannot lead to market inversions as the contract approaches maturity since $\lim_{t \to 0} \lambda_2 CY_t = 0$.

The July basis shows little response to the market liquidity variable developed in equation (5), suggesting that liquidity has not caused measurable distortions in the basis. Although the trading volume in FCOJ is small at times, it does not appear to have caused any abnormal basis adjustments over the July contract life. This analysis measures the basis over the life of one contract. In contrast, Ward's study uses a measure of the

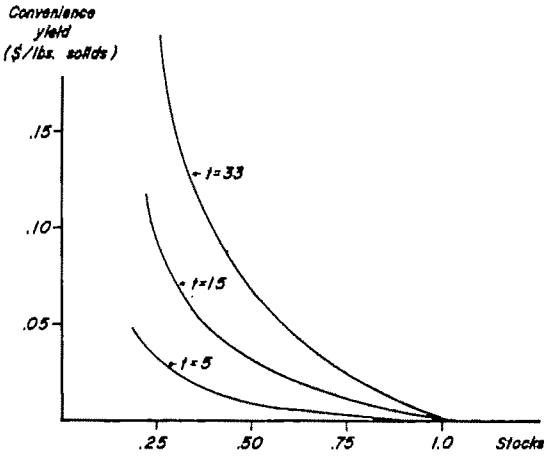

Figure 4. Convenience yield in the July FCOJ futures contract

[5] While the basis model is intended to deal primarily with the theory of storage and anticipatory effects, the relative large unexplained variation noted in equation (8b) can be troublesome to the trader. Much of the unexplained variation is related to the model's being estimated from weekly data. It is not abnormal to have lower R^2's for weekly versus longer time-series models. Furthermore, futures markets generally tend to respond to random information that does not immediately effect the cash market. Also, the futures price is selected at the weeks closing, and undoubtedly some variation is attributable to the price-selection criteria.

distortion based on a speculative index over all contracts during the closing period of the contracts.

Variables unique to the FCOJ basis model exhibit a pronounced effect on the basis residual, and an omission of these variables leads to a clear misspecification of the basis model. The variables *FB*, *FBA*, and *FZ* are unique to the concentrate market, yet they measure both the anticipatory effect from potential freezes and temporal differences in price adjustments. Although these phenomena are well known, they are seldom considered in any attempt to explain analytically the theory of storage (Brennan).

Considering first the anticipatory effect, a significant freeze bias is evident in equation (8b), table 1. The estimates from figure 3 indicated that the freeze period ends near the twenty-first week from contract maturity (mid-February). Hence, as long as $t > 21$, the results in equation (8b) show that the market includes a positive freeze bias where the basis exceeds the normal outlay from equation (2). The empirical measure of the freeze bias follows from equations (6), (7), and (8b), where

$$(11)\quad (\beta_1 + \beta_2 NBA_t)FB_t = (0.3259 - 0.2140 NSA_t)\ln\left(\frac{t - t^*}{\max t - t^*} + 1\right)$$

as long as $t > t^*$.

Equation (11) is illustrated in figure 5 where the darker curve represents the bias for a normal season (i.e., $NSA = 1.0$). Under these circumstances, the market generally reflects a freeze bias in the vicinity of 8¢ and then declines as the freeze period ends. In contrast, when the supplies are relatively small (i.e., $NSA < 1.0$) a freeze has a greater effect on the price since fewer stocks are available to offset any freeze loss. The market clearly reflects this potential in that the bias is above that shown for normal supply levels in figure 5. Similarly, if $NSA > 1.0$ there are more than normal inventories and a freeze potential does not have as great an effect on prices, as shown by the bias curve lying below the normal curve. For each level of *NSA* the bias remains relatively high through most of the freeze period and then declines rapidly as the period nears the end. This response is consistent with the situation where freezes are likely to occur any time within the freeze period until t is near t^*.

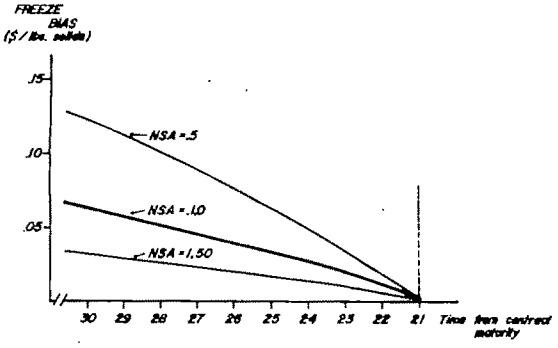

Figure 5. Freeze bias in the July FCOJ futures contract

The freeze bias can be expected to occur consistently even with extremely large crops. From equation (11), $NSA > 1.52$ before the freeze bias reduces to zero. However, the probability of *NSA* exceeding this level is extremely small.

The freeze bias in figure 5 provides a potential windfall to short hedgers. The basis widens at nearly the same time that many short-hedged positions are placed. The narrowing basis as the freeze period ends benefits the short hedger if the hedges are placed during those periods where the anticipatory effect is near a maximum. Hence correctly timing citrus hedging by both growers and processors to capitalize on the basis movements can lead to additional hedging gains (Niles and Ward). Also, an understanding of the crop size gives a trader some clue as to the potential basis gains that can be realized from short hedges.

While the freeze bias represents an anticipatory effect on the basis model, the actual freeze effect leads to price responses to factual information. The last variable in equation (8b) shows that the basis increases when a freeze occurs. Yet, after the freeze the basis again returns to the past freeze level assuming actual stocks are not changed. If temperatures drop to 24°, for example, $FZ = 4$, and the basis immediately widens by nearly 5¢. In succeeding weeks the basis adjusts back to the norm since both cash and futures markets then have time to assimilate information about the freeze.

The temporal basis response to varying freeze intensities illustrates to the long speculator that if his initial positions are placed at the proper time and price, then windfall gains are possible. However, if long positions

are placed after the market reflects the anticipatory effect of a freeze, then the potential speculative gains are greatly reduced. For the hedger, the freeze results are disturbing in that the futures side of a short-hedge position shows a loss. Yet, once the freeze information is assimilated into the cash market, the basis returns to the normal prefreeze level.

The closing period of the model is consistent with basis theory in that $\lim_{t \to 0} BR_t = \lambda_0 + \lambda_3 ML_t$ and C, RP, CY, FB, FBA, and $FZ = 0$. When the July contract ends most of the crop is harvested, and the freeze period is over. The closing spread shown in equation (2) approaches $\lambda_0 + \lambda_3 ML_t$. Since the liquidity parameter in the empirical model is insignificant, the closing basis approximates λ_0. In the perfect market the closing differential λ_0 represents the cost of delivery. However, the futures price generally reflects the lowest quality of product deliverable against the contract. Hence, λ_0 can be less than the cost of delivery. For the FCOJ July contract $\lambda_0 = -2.03¢$ per pound solids (see table 1, footnote d), which represents in part the quality differential between deliverable concentrate and concentrate normally used in commercial channels.

Conclusion

The basis model developed clearly supports both the theory of storage and establishes the necessity for measuring market bias. The results establish the credibility of the orange contract as a hedging tool and further illustrate certain basis patterns that can be used by the industry. Much of the basis theory cannot be clearly related to the practicing hedger nor is it necessary. Yet it is essential that traders using the market have confidence in its economic performance. Although the model does reflect the theory of storage, the actual basis residual model may differ substantially from the supply of storage models developed by Brennan and Weymar. Market bias can clearly cause deviations from the storage function. The cause of the bias must be recognized and remedied if needed. For the citrus contract, however, the freeze bias is a normal part of the anticipatory activity of the market and does not necessitate corrective action.

From a practical hedging standpoint the model provides useful guidelines for developing trading plans. In particular, the market does cover the cost of storage and exceeds this cost substantially during those periods where a positive market bias is evident. The model also suggests that traders must be prepared for basis shocks, especially during a freeze scare. The basis can widen and temporarily reduce basis gains from short hedging

From a government regulatory perspective, the empirical basis model supports the continuation of this contract if the market's performance is judged by conformity with theory. Likewise, the results have at least indirect implications for evaluating market manipulation on a large scale. Manipulative practices should visibly alter the basis performance relative to the basis theory and those unique factors measured in the basis residual model.

The Effects of Property Taxes and Local Public Services upon Residential Property Values in Small Wisconsin Cities

Melville McMillan and Richard Carlson

Contrary to the results of similar studies in metropolitan areas, this investigation found no evidence that local property taxes and public expenditures were capitalized into the value of owner-occupied homes in small cities despite their considerable dependence upon the property tax. This does not imply that residents of small cities are insensitive to fiscal differences but rather is evidence of the more elastic supply of land for housing in nonmetropolitan communities.

Key words: nonmetropolitan centers, property tax, property values, tax capitalization.

Several papers report on studies of the effects of local property taxes and public expenditures on residential property values (King; Oates 1969, 1973; Orr; Pollackowski; Smith). Typically, these investigations are conducted in metropolitan areas and, although the situation, model specifications, and results vary, they usually, though not always (e.g., Wales and Wiens, Heinberg and Oates), present some evidence that property taxes and the benefits of public services are capitalized into local property values. The extent of capitalization in centers outside the metropolitan area is less certain. Hyman and Pasour, who studied 106 towns throughout North Carolina, found little evidence of capitalization in the nonmetropolitan context. These contradictory results can be attributed to differences in interjurisdictional mobility and elasticity of demand for residential land between metropolitan and nonmetropolitan regions.[1] However, because of the substantial state support to local government and the resulting low property tax rates in North Carolina, residential demand may be less sensitive to tax-expenditure differentials there. If capitalization exists, it is more likely to be evidenced where property taxes are a more important source of local finance and interjurisdictional differences are greater. In order to test whether significant capitalization exists in nonmetropolitan areas where, as is more typical, local governments must rely heavily on local sources of revenue, a study of taxes, services, and property values was undertaken in Wisconsin, where the average effective local property tax rate is two-and-one-half times that of North Carolina.[2]

The Model

The relation between local property taxes, public services, and residential property values was estimated using a linear regression model. Since factors other than taxes and the provision of government services influence property values, several other variables are included in the attempt to hold the attributes

[1] Capitalization is facilitated by high interjurisdictional mobility and the inelastic supply of residential property within each tax jurisdiction. Hyman and Pasour argue that metropolitan areas are characterized by greater mobility and that the long-run supply of housing is considerably more elastic in North Carolina than in a large SMSA (standard metropolitan statistical area).

[2] Pasour reports that the average owner-occupied home has a market value of $12,500 and a property tax bill of $155—a tax rate of $1.25 per $100 of market value. This contrasts with $3.25 per $100 market value in Wisconsin. A large part of this difference stems from the greater state contribution to school districts current operating costs in North Carolina (70%) than in Wisconsin (30%).

of the house and community constant. Two indicators of housing quality are utilized—the median number of rooms and the percentage of homes built since 1950.

Home values are affected by the character of the community, which is influenced by numerous and often unquantifiable variables (e.g., style, beauty and maintenance of homes, types and uses of neighboring properties, and extent of local organizations and community activities). Since these may be related to income, two income variables are employed as surrogates for community character—median family income and percentage of families with incomes below the official poverty level. Both variables also reflect political considerations. Median income is important as it commonly is assumed to characterize the median voter whose preferences are expected to dominate local public decisions (see Barlow). The percentage in poverty allows for the heterogenity of the community's composition and presumably preferences that may modify political decisions relative to those made in a more homogeneous unit.[3]

The percentage of homes owner-occupied may reflect community character, but, more importantly, it should account for any institutional and behavioral factors that prevent the same rate of capitalization from applying to both owner and renter-occupied homes. In addition, it should eliminate the bias caused by the dependent variable referring only to owner-occupied homes, while the income variables are characteristic of homeowners and renters together.[4]

The location of a city with respect to a larger metropolitan area is expected to affect residential property values. Proximity to a metropolitan area provides greater access to employment and recreational opportunities and additional retail and service outlets than are available to more isolated communities. To test the importance of proximity to metropolitan areas, a proxy variable, the population of the nearest standard metropolitan statistical area (SMSA) divided by the distance of the city to the SMSA's principal population center, was used. Although out of state, Minneapolis-St. Paul was the nearest population area in some cases.

Having controlled for the influence of various other factors affecting the value of owner-occupied homes, the significance of the fiscal variables can then be isolated. If capitalization occurs, the effective full-value local property tax rate as a measure of local tax cost is expected to be an important determinant of home values. This is the rate after adjustment of the nominal local rates for variations in assessment practices among jurisdictions (i.e., assessed value/market value) and for the tax credit paid by the state to those tax districts whose full-value rate exceeds one-half the statewide average. By incorporating these adjustments, this rate is comparable among jurisdictions as it reflects fairly accurately the tax cost per (as specified here) hundred dollars of property value. Some variations can still occur if the amount of real estate in each class (e.g., mercantile, manufacturing, and residential) and the assessment ratios applied to them vary among tax districts. In such cases the actual tax rate applying to homes in two tax districts could vary somewhat, although the composite effective full-value tax rate is the same in each jurisdiction.

Indexes of the output of local public services are more difficult to acquire. In spite of attempts to devise such indexes, researchers must often resort to using expenditures as a measure of output particularly when considering the aggregate public service bundle (Hirsch, chap. 7). This procedure has serious drawbacks if economies of scale exist, production technologies differ, and/or resources are not homogeneous. Despite these shortcomings, there is little choice but to accept expenditures as a proxy for public output while recognizing its deficiencies.

Two expenditure variables are used as output proxies: school operating expenditures per pupil and nonschool expenditures (excluding debt service) per capita. School expenditure is more likely to be significant since it represents the larger portion of total local expenditures, and people readily perceive those benefits school expenditures provide. Although school expenditures can sometimes serve as a proxy for the output of other local public services, it would be a poor

[3] Median family incomes may also reflect more traditional demand and supply effects. Higher income generally means larger expenditures on housing but may also imply higher costs of construction where incomes and wage rates are closely related.

[4] Oates uses the percentage in poverty as an adjustment to the assumed bias in the income variable with respect to home ownership. The percentage owner-occupied better serves the function here because the poor are more likely to own their own homes in small than in large urban centers.

index here as there is little relation between school and nonschool expenditures in these cities ($\rho = 0.076$). Including nonschool expenditures per capita accounts separately for benefits derived from nonschool services. Furthermore, it could correct for any bias in the estimation of the effect of the tax rate due to a positive association between nonschool expenditures and tax rates, although that is not a problem in this instance.

The empirical specification of the model is

$$(1) \qquad V = f(T, S, N, R, B, Y, L, \varnothing, U),$$

utilizing the notation defined in table 1. The model is tested using data for all incorporated Wisconsin cities meeting three conditions: (*a*) having a high school, (*b*) lying outside SMSA's, and (*c*) with a 2,500 to 25,000 person population. Sixty-five cities satisfy these criteria. The model is estimated using two-stage least squares (2SLS) regression. Ordinary least squares (OLS) estimates are expected to incorporate some simultaneous equation bias since the independent variables of concern (tax rate, school expenditure, and nonschool expenditure) depend to some extent upon the dependent variable—property value. If, as is shown to be the case here, the simultaneity is serious, the OLS estimates are not reliable. For comparative purposes, the Hyman and Pasour model and the Oates model are both estimated using the same data.

Empirical Results and Analysis

In order to remove the possibility of simultaneous equation bias, two-stage least squares procedures are used to predict values for the fiscal variables that, purged of their correlation with the error term, could be used to obtain an unbiased estimate. In the calculation of estimated values of the variables several additional variables believed to influence tax rates and public expenditures are included: (*a*) the percentage change in population from 1960 to 1970, (*b*) the assessed valuation of mercantile and manufacturing

Table 1. Variable Symbols, Units, and Expected Signs

Symbol	Variable Definition	Expected Sign
	Variables Appearing in Equation (I)	
Dependent variable		
V	Median value of owner-occupied homes, 1970[a] ($100)	
Fiscal variables		
T	Effective general property tax rate, 1970[b] ($/$100 market value)	−
S	School expenditures per pupil, 1969–70[c] ($)	+
N	Nonschool expenditures per capita, 1969–70[d] ($)	+
Nonfiscal variables		
R	Median number of rooms per owner-occupied unit, 1970[a]	+
B	Percentage of homes built since 1950, 1970[a]	+
Y	Median family income, 1970[e] ($1,000)	+
L	Percentage of families with income less than the 1970 poverty level, 1970[e]	−
$\varnothing$	Percentage of homes owner-occupied, 1970[a]	?
U	Population of nearest SMSA divided by distance of the city to the nearest principal population center in the SMSA (includes SMSA's in other states if closest), 1970[e,f] (1,000/miles)	+
	Additional Variables Appearing in Equations (II) and (III) (Hyman and Pasour and Oates Versions of the Model)	
D	Percentage change in number of owner-occupied units, 1960–70[a]	?
E	Local property taxes per capita, 1970[b] ($)	+
M	Distance to nearest principal city in nearest SMSA (includes SMSA's in other states if closest)[f] (miles)	−
P	Population, 1970[e] (1,000)	+

property, (*c*) the average number of years of education of adults twenty-five years of age or over, and (*d*) the proportion of the total population attending either primary or secondary school. The Oates 1973 model also includes the proportion of homes owner-occupied in the first-stage estimate since this variable was not contained in his model's initial specification.[5]

A summary of the results obtained by 2SLS is shown in table 2. The specifications of the model chosen for this study are equations (Ia) and (Ib). (The Hyman and Pasour and the Oates 1973 versions are equations (II) and (III), respectively.) Of the nonfiscal variables in equation (Ia), the coefficients of the proximity to SMSA measure, the percentage of homes owner-occupied, and the percentage of new homes all display some degree of significance. The assumed signs appear in the results. The percentage of owner-occupied units, which does not have a sign specified in the model, has a negative sign, indicating that owner-occupied homes have a higher median value where renter-occupied homes are a larger portion of total units. This probably results partly because renting is more important in larger and growing cities where home values tend to be higher.

The coefficients of the median number of rooms, median family income, and the percentage of families with income less than the poverty level are all insignificant. However, a substantial amount of collinearity exists between income and the percentage of poor, homes built since 1950, and the tax variable ($\rho = -0.808$, 0.643, and 0.504, respectively). Also, the median number of rooms is somewhat correlated with several of the other measures, but its low coefficient is most likely the result of there being little spread in the data (5.3 to 6.2 rooms). Although including all these variables is justifiable, especially since we are not concerned principally with estimating the coefficients of the nonfiscal variables, for practical purposes equation (Ib) is also presented, which is like equation (Ia) except that the variables median income and median number of rooms are deleted. The only effect is to increase the *t*-value of some coefficients, most notably that of the percentage of homes owner-occupied.

In neither equation are the coefficients of the fiscal variables significant. This indicates that in these communities the benefits and

[5] In the strict sense this is not a 2SLS model but a form of instrumental variables. A true 2SLS model uses all the predetermined variables from a completely specified system of equations in the first-stage estimates. As a full model has not been specified here, our selection of additional predetermined variables may be incomplete, in which case the method used is instrumental variables. However, as the procedure adopted here parallels that referred to as 2SLS by others writing on this topic (e.g., Oates 1969, 1973), in order to avoid confusion in relating to their work we continue the inprecise convention of calling this technique 2SLS, while recognizing that it may in fact be instrumental variables depending upon the completeness of the selection of the predetermined variables.

Table 2. Summary of Two-Stage Least Squares Regression Results

Equation (Ia)	$V = 225.5 - 26.65T^* + 0.0862S^* - 0.0899N^* + 0.695R + 1.443B + 0.560Y$ (0.95) (−0.80) (0.45) (−0.49) (0.04) (3.21) (0.10) $- 1.055L + 0.2555U - 1.310\emptyset$ (−0.81) (1.86) (−1.75)	$R^2 = 0.83$
Equation (Ib)	$V = 239.3 - 28.45T^* + 0.0916S^* - 0.1016N^* + 1.438B - 1.2224L + 0.2491U$ (1.73) (−1.63) (1.10) (−0.74) (3.39) (−1.42) (1.98) $- 1.3159\emptyset$ (−3.06)	$R^2 = 0.82$
Equation (II)	$V = 215.6 - 13.13T^* - 0.0313E^* - 9.717R + 14.13Y + 0.4684U - 1.555\emptyset$ (1.23) (−0.41) (−0.30) (−1.01) (3.08) (3.31) (−4.24) $- 0.0953P + 0.0950D$ (−0.18) (0.48)	$R^2 = 0.74$
Equation (IIIa)	$V = -1589.5 + 85.66(\ln T)^* + 262.6(\ln S)^* - 19.62(\ln N)^* - 23.24R + 2.077B$ (−2.05) (0.61) (2.02) (−0.64) (−0.77) (2.39) $+ 8.500Y + 1.018L + 0.961(\ln M)$ (0.81) (0.44) (0.08)	$R^2 = -0.08$
Equation (IIIb)	$V = -271.9 - 47.11(\ln T)^* + 74.01(\ln S)^* - 5.44(\ln N)^* + 4.03R + 1.810B$ (0.26) (−0.40) (0.48) (−0.32) (0.17) (4.25) $+ 2.177Y - 0.733L + 1.353(\ln M) - 1.173\emptyset$ (0.33) (−0.44) (0.25) (−1.32)	$R^2 = 0.80$

Note: Numbers in parentheses are the *t*-statistics. The asterisk indicates an endogenous variable.

costs of public services have not been capitalized into the value of owner-occupied homes. This result is substantiated by the fact that the nonfiscal variables alone account for 80% of the variation, while the fiscal variables, when regressed against property values, explain very little.

To check the results two alternative specifications of the model are estimated. Equation (II) is the Hyman-Pasour model fitted to Wisconsin data. Different nonfiscal variables are the population of the community and the percentage change in the number of owner-occupied homes for 1960 to 1970. Neither variable has a significant coefficient. The coefficient of population may be insignificant because both costs and benefits of living in urban centers increase with population. Since they were unable to obtain census data on the percentage of homes built since 1950 at the time of their study, Hyman and Pasour used the change in the number of owner-occupied homes from 1960 to 1970 as a second-best measure of the average age of homes. Correlation between these two variables ($\rho = 0.263$) indicates that, for Wisconsin data at least, it is not a particularly good substitute.

The coefficients of certain other nonfiscal variables are significant. Both the percentage of homes owner-occupied and the measure of proximity to metropolitan centers have significant coefficients. In the absence of the poverty measure, the coefficient of median family income is significant.

After testing several alternative measures of government output, Hyman and Pasour let the data choose the variable to be included in their final equation, local property taxes per capita, although it is further removed than expenditures from the benefits of public services. Neither this coefficient nor that of the other fiscal variable, tax rate, are significantly different from zero.

The revised Oates 1973 model fitted to the Wisconsin data (equation (IIIa), table 2) provides a second alternative specification. Oates assumed that the tax rate, the spending variables, and the distance to the metropolitan center would have an exponential relation and, therefore, used a logarithmic transformation of these four variables, which did improve explanatory power in his study. The use of the logarithmic form on these data does not appear justified. Because individual family and home data are aggregated into a single observation for each community and the level of the fiscal variables does not differ by much due to institutional rigidities, the spread of the data is not great.[6] Thus, over the range of data likely to be encountered, logarithmic and linear functions will not differ substantially. It is only in this form of the model that a fiscal variable displays a significant coefficient, i.e., nonschool expenditures per capita. But the R^2 in this case is only -0.08. Although R^2 in 2SLS models usually appears between zero and one, zero or negative values are possible when residuals are correctly calculated and need not indicate that the results should be discarded (Tomek). Since the other two models contain the additional variable, percentage of all units owner-occupied, this variable is added to Oates's original specification and estimated as shown by equation (IIIb) of table 2. With the inclusion of this variable, R^2 increases to 0.80, but the coefficient of school expenditure per capita becomes insignificant.[7] The only variable to have a significant coefficient in both forms of the Oates model is the percentage of homes built since 1950. While satisfactory in his metropolitan context, the use of distance alone rather than population divided by distance does not perform well as a measure of accessibility in this nonmetropolitan situation.

Implications

Although equation (I) is preferred theoretically and explains better than the other two models or their variations, in general the performance of the three models is consistent and largely as expected. Overall, certain nonfiscal factors (e.g., the percentage of homes built since 1950, proximity to metropolitan areas, and the percentage owner-occupied) appear to influence the value of owner-occupied homes in small urban centers, but fiscal factors apparently are unimportant.[8] As

[6] While tax rates range between 26.15 and 40.23 mills, they have a standard deviation of 3.278 about a mean of 32.45 mills. School expenditures vary from $513 to $836 per pupil with a standard deviation of $70.53 about the mean of $656.02.

[7] The fit and significance of coefficients of equations (Ia) and (Ib) are also sensitive to the inclusion of owner-occupancy, although that of equation (II) is less so, apparently because income and population substitute is part of that variable.

[8] In contrast, OLS estimates yield significant coefficients for the tax rate and school expenditure variables that are consistent with full capitalization if the rate of interest is 5% and property life is forty-five years. For example, increasing property taxes by $100 to finance an additional $100 of school expenditure has

property taxes in Wisconsin are substantial, the fiscal variables are not irrelevant because of relatively small local contributions but rather because of the structure of the small urban center housing market.

While the short-run supply of improvements is likely to be quite inelastic and the price of existing units sensitive to tax rates, the long-run supply of structures to residential housing is generally believed to be quite elastic (Muth). As a result of the supply of capital to housing being elastic, increased property taxes must either be shifted forward to consumers through higher prices or backwards to land as the tax is capitalized into lower property values. The direction and extent of the shifting (and capitalization) depends on the relative elasticities of supply and demand. On the supply side it is reasonable to expect that in most instances the long-run supply of land for development is elastic (McMillan). An exception occurs within major urban areas where, other than at the urban fringe, the amount of land available for development in each jurisdiction is relatively small and its alternative uses limited. Consequently, the supply of housing is expected to be more inelastic in jurisdictions within metropolitan areas where the supply of developable land is more restricted and the value of the land to residential improvements is greater than in small urban centers.[9]

The metropolitan environment also affords greater opportunity for home buyers to react to differences in property tax rates and public services among jurisdictions. Because of the multiplicity of municipalities within close proximity to one another, individuals are not restricted by time and distance to living and working in the same jurisdiction but are able to select among municipalities on the basis of tastes and preferences. That consumers of housing respond to local fiscal considerations (outputs and costs) in selecting their community of residence was postulated by Tiebout, and Oates's work is considered evidence that account is taken of fiscal differentials as people compete for the preferred sites in the metropolitan area.[10]

Conversely, in nonmetropolitan areas, location alternatives are more restricted. The location of employment opportunities are much more influential in determining an individual's place of residence; unlike the Tiebout model, individual's incomes are to some extent location specific. Within the vicinity bounded by travel costs, the choices may be quite limited. In many rural localities, if one wishes the benefits of basic urban services, they may be available from only one municipality. As a result, the individual's ability to express satisfaction with the public sector, or even to realize the range of alternatives available, is constrained, making remote the likelihood that differentials in the quality of service, particularly moderate ones, will be reflected in local property values.[11]

That the demand for housing is less elastic and the supply more elastic in small urban than metropolitan areas is consistent with capitalization of taxes and public expenditures being evidenced only in the latter. The failure of intercity fiscal differentials to be reflected in property values in a situation where local taxes are substantial is evidence that the supply of residences in nonmetropolitan urban centers is elastic. Of relative elasticities of demand less can be said as noncapitalization does not indicate that the Tiebout process does not operate to some degree among nonmetropolitan cities, although it is not expected to be as pronounced as within metropolitan areas. People may still prefer and seek out those communities offering greater net fiscal benefits, but because of the high elasticity of housing supply the impact is more upon those communities' growth rates than their property values. Because the number of sites in a specific jurisdiction may be limited in metropolitan areas, the impact upon property values is greater.

---

a net effect of reducing the median home value by $811 (i.e., $1,296 − $485). This comparison of OLS and 2SLS results differs substantially from that of Oates who observed no significant difference between the two methods and that of Hyman and Pasour who, due to the lack of variation in the predicted value of the effective property tax rate, found 2SLS unsatisfactory. Because of the importance of property taxes in Wisconsin, 2SLS procedures are believed necessary to account for the relationships between property values and the fiscal variables, which lead here to dismissing the OLS results as spurious.

[9] Hyman and Pasour also believe that more restricted entry to the construction industry in metropolitan areas makes supply more inelastic there.

[10] Oates's results are based on a cross-sectional study of fifty-three residential communities in northeastern New Jersey, all located within the New York metropolitan region (1969).

[11] Instead, rural communities displaying superior public sector performance may be characterized by more rapid growth rather than by higher property values. Weaver and McMillan found that during the 1960s manufacturing employment grew most rapidly in those cities believed to offer a higher quality of public service. Higher local tax rates detracted from local growth but had a very small effect.

In a time when a reduction in the dependence of local school finance upon the property tax is sought, a major implication of the results of this study is that decreasing property taxes will likely not lead to sizable capital gains for owners of residential property in small cities. Some increase could arise due to capitalization in markets where the supply of housing is less elastic, depending upon the degree of substitutability of property among the elastic and inelastic markets. In contrast, evidence from other studies suggests that the owners of farm real estate (Pasour) and metropolitan residences can expect their property values to appreciate if property taxes were reduced.

A Quantitative Investigation of a Political Economy—The Israeli Dairy Program

Pinhas Zusman and Amotz Amiad

The formation of economic policy reflects the underlying economic and political structure. A game theoretic approach is employed in formulating the political structure, which is then combined with the economic structure to yield a model of a political economy. The parameters of the model are estimable from observed behavior. A model of the Israeli dairy program is constructed and estimated. The power relations and the structure of the conflict among interest groups are investigated.

Key words: dairy program, economic policy, interest groups, Israel, political power.

A political economy, as conceived in the present study, is a system of economic and political relations that together determine the values of the endogenous economic variables as well as those of the policy instruments. In dealing with such systems, not only are we interested in the question, "Given the values of the policy instruments, how are values of the endogenous variables determined?" but also in the question, "How are the values of the policy instruments determined?"

In attempting to answer the last question, one could adopt Tinbergen's normative approach and hypothesize an optimizing behavior on the part of policy makers (1956). The political-economic structure will then consist of the economic structure, a policy objective function, and various constraints on the policy instruments. Indeed, several successful attempts at estimating the policy objective function have been reported (Friedlander).

An alternative, and more realistic, approach was adopted by Rausser and Freebairn. They recognized the bargaining nature of the political process but claimed that the outcome of the process can be predicted by maximizing an appropriate "policy preference function." Their main contribution is in recognizing the role of pressure groups in the political process and in the corresponding formulation of the policy preference function in terms of the groups' objectives. However, Rausser and Freebairn did not provide a formal structure of political economy, and it is not clear why a policy preference function should exist at all. Furthermore, even if its existence is admitted, the problem of its interpretation is yet to be settled.

A formal structure of a political economy was proposed by Zusman. In his model the political power of the various interest groups is explicitly recognized, and the resulting political economic equilibrium is a solution to the corresponding bargaining game. The formulation also allows for the estimation of political power parameters, and it is employed in investigating the Israeli dairy program. However, while Zusman's paper took the interest groups' objective functions as given, the present analysis focuses on their identification and measurement and also seeks answers to the questions, "What is the structure of the underlying conflict, and does the prevailing power structure allow for further policy improvements?"

The Conceptual Structure of a Political Economy

The structure of a political economy consists of the following components: (*a*) the economic structural equations; (*b*) the set X_0 of feasible policy instruments; (*c*) the policy

Pinhas Zusman is a research economist at the Development Research Center of the International Bank for Reconstruction and Development on leave from the Hebrew University of Jerusalem, and Amotz Amiad is a lecturer at the Hebrew University of Jerusalem.

The authors' conclusions are their own and not those of the International Bank for Reconstruction and Development.

The conditions assuring the existence and uniqueness of a solution to the problem thus depend on the set of constraints in the programming problem, equation (2). Intuitively, the conditions are rather mild—the efficiency frontier determined by $G(x_0) \geq 0$ and $u(x_0)$ should be continuous, and the tangent plane to it should have positive coefficient everywhere. There should exist possible trade-off relationships between the objective functions of every pair of interest groups.

The solution of the programming problem for $n = 1$ is presented graphically in fig 1. In the application below, a modified gradient method is used to obtain the desired values.[4]

[4] In addition to its usefulness in analyzing behavioral systems, programming problem, equation (2), can be instrumental in developing possible improvements in existing policies. Since the gains are distributed equally among all interest groups, the proposed political changes are more likely to be accepted. The solution procedure, developed by the present authors, consists of a sequence of restricted steps. In each step the objective function (V) is increased by solving a local linear programming problem obtained by an appropriate linearization of the system. The solution in each step serves as the linearization base of the next step. The sequence commences at the observed solution (x_0') and leads to x_0^*, where the conditions for maximum V are met. A description of the solution algorithm is available from the authors.

The Israeli Dairy Program

Government intervention in the Israeli dairy market during the last two decades has been significant and consistent. Imports of dairy products were limited to the bare minimum and were subjected to a sizable duty. Farm prices for raw milk were guaranteed at rather high levels, so that production of raw milk had to be controlled through a system of production allotments. Consumer prices were set at low levels, which failed to cover processors' total costs (raw material plus processing costs), involving the government in high subsidies. A peculiar feature of the subsidy program was the differential support to the various dairy products. Consumer prices of fluid milk were set at high levels, so that only a small subsidy was required, whereas other dairy products enjoyed a heavy subsidy and low consumer prices. This mode of government intervention persisted throughout the entire period, surviving several heated debates concerning its desirability.

The rest of this study is devoted to the exploration of the determinants of the political-economic equilibrium in the Israeli dairy

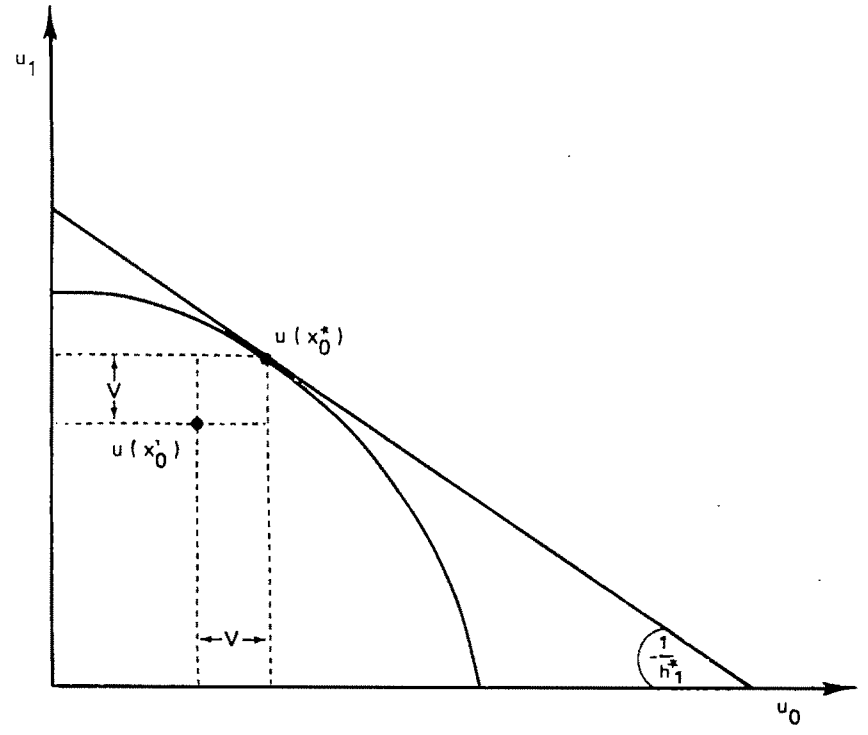

Figure 1. The estimation of a theoretical solution in a political-economic system with two players

market. To this end the model presented in the preceding sections is applied to conditions prevailing in 1968–69 (October 1968–September 1969).

The Economic Structure of the Israeli Dairy Market

To simplify the analysis, all dairy products were aggregated into two main groups: fluid milk and other dairy products. The estimated demand functions for 1968–69 were

$$q_f = 188{,}348\ P_f^{-0.05}, \tag{3}$$

and

$$q_p = 778{,}123.7\ I^{0.773} P_p^{-1.21}, \tag{4}$$

where q_f is annual demand for fluid milk (expressed in kiloliters raw milk equivalents); q_p is annual demand for other dairy products (expressed in kiloliters raw milk equivalents); I is total per capital consumption expenditures (IL [lira] per capita); P_f is consumer price of fluid milk (IL per kiloliter raw milk); P_p is consumer price of other dairy products (IL per kiloliter raw milk). The demand equations were derived by fitting demand elasticities estimated by Rimland to 1968–69 prices, quantities, and per capita consumption expenditures (Israel Central Bureau of Statistics).

Worth noting is the low price elasticity of demand for fluid milk (−0.05) as compared to that of other dairy products (−0.121). As will be asserted subsequently, the differential subsidy policy stems largely from this difference in the price elasticities.

Total domestic production of raw milk is an important policy instrument. Since fluid milk cannot be imported, domestic production of raw milk is first allocated to this utilization, the remainder is diverted to other dairy products. Excess domestic demand for dairy products is ordinarily met by imports of powdered milk and butter. These relations are represented by the following balance equations:

$$Q = q_f + q_i \tag{5}$$

and

$$q_{pm} = q_p - q_i, \tag{6}$$

where Q is total domestic production of raw milk (kiloliters); q_i is utilization of domestically produced raw milk for other dairy products (kiloliters); and q_{pm} is imports of powdered milk and butter (expressed in kiloliters of raw milk equivalents).

Two politically and economically meaningful sectors of dairy farms were distinguished: large cooperative farms (kibbutz farms) and family farms (moshav farms). The two sectors apply different production methods and also constitute distinct political organizations. The intersectoral allocation of total milk production is an important policy instrument. We thus have

$$Q_1 = kQ, \tag{7}$$

$$Q_2 = (1 - k)Q, \tag{8}$$

$$C_1 = 378.5Q_1, \tag{9}$$

and

$$C_2 = 418.8Q_2, \tag{10}$$

where Q_1 is production of raw milk by kibbutz farms (kiloliters); Q_2 is production of raw milk by moshav farms (kiloliters); k is share of kibbutz farm in total domestic production of raw milk ($0 \leq k \leq 1$); C_1 is total cost of milk production by kibbutz farms (IL); and C_2 is total cost of milk production by moshav farms (IL). Cost figures were obtained from the Institute of Farm Income Research. Owing to economies of scale, the cost of milk production in moshav farms exceeds that of the kibbutz. The constant average cost formulation was adopted in order to facilitate the analysis.

Consumer prices are set by the government at relatively low levels. Processors' returns from sales are, therefore, supplemented by a handsome government subsidy. About 90% of the raw milk is processed in dairy plants owned by farmers' cooperatives. Farm prices of raw milk are determined by total value of sales plus subsidy net of processing cost as follows:

$$C_p = 66.0q_f + 219.0q_i, \tag{11}$$

$$R = P_f q_f + P_p q_i + SQ, \tag{12}$$

and

$$P_m = \frac{R - C_p}{Q}, \tag{13}$$

where C_p is total processing cost (IL); R is total revenue, including subsidy receipts (IL); S is average subsidy (IL per kiloliter raw milk); and P_m is farm price for raw milk (IL per kiloliter raw milk). Equation (11) relates the total cost of processing to the quantities of the various dairy products.[5] Equation (12) relates total revenues to sales and subsidy receipts, while equation (13) is a definitional relation.

The endogenous variables are q_f, q_p, q_i, q_{pm}, Q_1, Q_2, C_1, C_2, C_p, R, and P_m, eleven variables in all. Their values are determined by equations (3) through (13). The policy instruments are P_f, P_p, Q, k, and S. How are values of the policy instruments determined? To answer this, one must investigate the political relations in the system.

The Political Structure of the Israeli Dairy Market

Three interest groups were distinguished in the analysis: kibbutz farms, moshav farms, and consumers. Both the kibbutz and the moshav groups are well organized and influential. They form powerful blocks in the political parties participating in the coalition government, and their representation in the legislative and executive branches of government exceeds substantially their share in the population. They also control all agricultural marketing boards and man important positions in the Ministry of Agriculture. Moshav farmers are more numerous than kibbutz members but are somewhat less active politically.

The objective functions of the farmers' groups were first identified with their net income, i.e.,

$$u_1 = P_m Q_1 - C_1 \tag{14}$$

and

$$u_2 = P_m Q_2 - C_2. \tag{15}$$

Consumers, in general, constitute a diffused political entity. Their awareness and sensitivity to changes in the policy parameters are low and apart from a very weak Consumers Council lack any formal organization. The Israeli press may at times reflect consumers' attitudes very effectively but is very rarely interested in the dairy market as such. For a variety of reasons, the general trade union organization, the Histadrut, has undertaken to represent consumers' interests. Since the Histadrut is politically powerful, consumers' power has thus been reinforced.

The objective function of the consumers' group has been identified with the consumer surplus:

$$u_3 = 198{,}261\,(P_f^{*0.95} - P_f^{0.95}) - 3{,}705{,}348\,I^{0.773}(P_p^{*-0.21} - P_p^{-0.21}), \tag{16}$$

where $P_f^* = P_p^* = 1{,}000$ are arbitrary high values of P_f and P_p, respectively.[6]

Ultimate policy decisions with respect to the dairy program are made by the Minister of Agriculture and the Minister of Treasury. It is rather difficult to determine the objective function of this policy-making group. Nevertheless, given the dominant position of the treasury in the Israeli government, it is reasonable to assume that considerations related to tax collection or alternative claims on public funds are of primary importance. The objective function of the policy makers is identified with the net cost of the dairy program, which is obtained by deducting the proceeds from duties levied on imports of dairy products from the total subsidy expenditures. Thus,

$$u_0 = -SQ + 60.4q_{pm}. \tag{17}$$

Besides the ordinary nonnegativity constraints, which all prices and quantities must obey, two additional constraints have been added. The first is technical: fluid milk cannot be imported, i.e.,

$$q_p - q_{pm} \geq 0. \tag{18}$$

The second is definitional: the shares of the kibbutz farms in total production cannot exceed 100%:

$$0 \leq k \leq 1. \tag{19}$$

An important constraint is implicitly as-

[5] Processing cost of fluid milk is based on data obtained from Koisch and Zukerman. The corresponding cost for other dairy products was obtained by applying equations (11), (12), and (13) to 1968–69 figures.

[6] In the present formulation the exact values of P_f^* and P_p^* are of no concern, since they affect only the constant term in the maximand W. This is because the power coefficients were assumed to be constant. In the more general case, where the power coefficients vary, the values of P_f^* and P_p^* are important and should not be selected arbitrarily.

sumed: no direct income transfers are permitted.

The Political-Economic Equilibrium in the Israeli Dairy Market

The solution procedure was first employed in analyzing the political-economic relations represented by equations (3) through (19). The results of the analysis, i.e., the theoretical values of the policy instruments, the power coefficients (H_i^*), and some endogenous variables, are given in column (3), table 1, where they are compared to the observed values of the respective variables (column (2)).

At first glance, the results were very discouraging. Clearly, there is a sizable discrepancy between the observed and calculated values. The model does very poorly in explaining actual behavior. Why did politicians stick to such an inefficient economic policy? As the analysis suggests, changing the prevailing policy could raise the objective function of every interest group by some IL11,786,450, a significant improvement. It is unlikely that this behavior be attributed to ignorance. In fact, for many years it has been argued by some government officials and economists alike that the Israeli milk program is no good, Israel is producing too much milk and importing too little, the subsidy is excessive, and production should be reallocated among farmers in a more efficient way. These arguments were opposed vehemently by farm leaders, in spite of the fact that producers could share the benefits accruing from a revised policy. Consequently, no such change ever took place. The ignorance hypothesis was, therefore, rejected.

An alternative hypothesis had to do with the producers' objectives. In the political process, farmers are represented by their leaders. Farm leaders' goals do not necessarily coincide with those of the farmers. While each individual producer may be interested above all in his own net income, the leader's objectives are more complex. In particular, he must accommodate his constituency in some measure. From the point of view of the individual producer, the milk price is given, but his production quota is allocated to him through his representatives. Hence, farm leaders are under constant pressure to raise production quotas; the higher the milk prices, the greater the pressures. Therefore, it seems reasonable to regard production quotas as another target variable of the farm sectors. Equations (14) and (15) were, therefore, replaced by

$$u_1 = \left(\frac{Q_1}{Q_1'}\right)^{\beta} [P_m Q_1 - C_1], \tag{20}$$

and

$$u_2 = \left(\frac{Q_2}{Q_2'}\right)^{\beta} [P_m Q_2 - C_2], \tag{21}$$

where Q_1' and Q_2' are the observed 1968–69 values of Q_1 and Q_2, respectively, and β is an unknown nonnegative parameter reflecting the importance that farm leaders attribute to the production quota. The higher the value of β, the more desirable is a high quota relative to its 1968–69 value. The calculated equilib-

Table 1. Actual and Equilibrium Values of Economic Variables and Power Coefficients, 1968–69

Variables	Actual Values	Calculated Values		
		$\beta = 0$	$\beta = 2$	$\beta = 3$
Consumer price for fluid milk (P_f)	495.4	522.2	581.3	587.5
Consumer price for other dairy products (P_p)	480.4	422.2	429.5	429.6
Total domestic production (Q)	366,713	137,742	286,394	325,114
Domestic production of other dairy products (q_i)	228,606	0	149,387	188,180
Import of dairy products (q_{pm})	18,000	288,699	133,456	94,532
Share of kibbutz farms in total production (k)	0.459	0.541	0.495	0.480
Subsidy rate (S)	118.9	227.7	147.2	131.2
Farm price of raw milk (P_{m1})	443.6	683.9	503.5	472.8
Power coefficient, kibbutz farms (H^*_1)	—	0.936	1.134	0.906
Power coefficient, moshav farms (H^*_2)	—	1.080	2.241	2.039
Power coefficient, consumers (H^*_3)	—	0.996	0.973	0.975
Gain in objective function $u_i(x^*_0) - u_i(x'_0)$	0	11,786,450	1,605,881	740,674

rium values corresponding to $\beta = 2$ and $\beta = 3$ are presented in columns (4) and (5), table 1.

Although it is not entirely satisfactory, the explanatory power of the model is raised considerably by the inclusion of production quotas as target variables of the farm sectors. Thus, with $\beta = 3$, the theoretical level of domestic production is much closer to the actual one, an outcome attained through import substitution. The theoretical farm price, subsidy rate, and production allotments are also more in line with the observed values. However, the theoretical consumer prices differ substantially from the actual prices. Furthermore, the predictive power of the model with respect to the consumer price of fluid milk is weakened. Interestingly, despite the sizable differences between the actual consumer prices and the theoretical ones, the potential gains from the efficient policy is relatively small—about IL741,000 per interest group. If there are some secondary political and administrative considerations in favor of a smaller gap between consumer prices of the two products, the failure of the model should not be overrated. Indeed, any such model is likely to fail in discerning variations to which the objective functions are insensitive. Finally, it is also possible that erroneous price elasticities were used,[7] or policy makers may have acted on erroneous ones (for more on this "problem of conformity," see Tinbergen 1954), or both. Evidently, errors in the estimation of the economic structural parameters may bias estimates of the power coefficients. Thus, the estimated power of the consumers' group depends on the price elasticities of demand used in the analysis. The greater the elasticity, the more sensitive is the consumer surplus to variation in prices and the more sensitive is the estimates of consumers' power. Since the elasticities of demand for dairy products are relatively small, we conjecture that the sensitivity of the estimates is also low.

Consumer price relationships deserve some further attention. First, the actual imputed value of raw milk allocated to the production of fluid milk, net of processing cost, is IL429.4 per kiloliter, while the corresponding value of raw milk processed into other dairy products is only IL261.4 per kiloliter. Recalling the difference in the elasticities of demand for the two products, the observed pricing behavior obviously involves an element of price discrimination. The surprising finding of the analysis is, however, that a policy change directed at the simultaneous increase in the well-being of all groups entails a further accentuation of the discriminating behavior. This is another manifestation of the "second-best" principle.

The introduction of milk production quotas as target variables of the farm sectors sheds new light on the power structure. Moshav farms now appear more powerful, reflecting the power relations that enable producers to force imports down and domestic production up, despite governmental opposition.

At this point one may wish to examine the normative implications of the analysis. Clearly, if one adheres to economic surpluses as the appropriate measures of social welfare, the Israeli dairy program is badly distorted. Even with the given policy instruments, the well-being of every group could be greatly enhanced. (This can be verified from the last row in table 1.) However, given that farm leaders continue to emphasize the output level as a desired policy goal, and given their political power, there is little scope for further improvements (see column 5, table 1).

The Internal Structure of the Political Conflict

The analytic path followed in the present study leads to one more interesting relationship having to do with the internal structure of the conflict. Consider the matrix K whose elements k_{ij} are the derivatives of the objective functions with respect to the policy instruments evaluated at the equilibrium levels, i.e., $k_{ij} = \partial u_i / \partial x_{0j}$, evaluated at $x_0 = x_0^*$. This matrix is named the conflict matrix, since it expresses the conflict among interest groups concerning the desired changes in policy instruments. Clearly, the k_{ij}'s cannot have the same sign for all i. But there are more interesting structural aspects traceable through the conflict matrix.

Consider, for instance, the conflict matrix

[7] Thus, the standard error of estimate reported by Rimland for the price elasticity of demand for fluid milk is 0.034 ($t = 1.47$). Since the price elasticity of demand for other dairy products was obtained by combining estimated elasticities for several products, the corresponding statistic is not available. However, here, too, considerable errors in the estimates are not unlikely.

Table 2. The Conflict Matrix, Model I

Interest Group	Policy Instruments: Consumer Price of Fluid Milk (P_f)	Consumer Price of Other Dairy Products (P_p)	Domestic Production (Q)	Production Share of Kibbutz Farms (k)	Subsidy Rate (S)
Government (u_0)	−112	125,690	−156.7	0	−286,390
Kibbutz farms (u_1)	46,818	40,125	80.5	76,296,000	100,500
Moshav farms (u_2)	35,818	40,107	29.1	−38,649,000	76,890
Consumers (u_3)	−137,010	−282,720	0	0	0

Note: Model I corresponds to $\beta = 2$.

presented in table 2, which corresponds to the model developed earlier (model I). Obviously, the two producers' groups agree on the desired direction of changes in all policy instruments except their relative shares of domestic production. Furthermore, the other interest groups are indifferent with respect to this particular instrument. Hence, relative shares are expected to be settled as an internal matter of the producing sectors. Having settled the internal conflict, producers are expected to form a coalition vis- à- vis the other groups. But this is still a controversy-ridden coalition, for its members seem to disagree, for instance, on the merits of an increase in domestic production as compared with changes in other instruments. True, this may be a mere tactical point, but it is a disagreement nonetheless.

Additionally, the conflict on other policy instruments emerges as a complex structure involving all parties. The resolution process is, thus, complicated considerably. It turns out, however, that model I is not unique and the conflict may be restructured. For instance, why should the subsidy rate be regarded as the policy parameter while assigning the producer price of raw milk the role of an endogenous variable? Why not exchange roles, setting a fixed producer price and adjusting subsidies in accordance with actual sales. In fact, negotiations between farmers and the government were actually conducted in terms of a target producer price. The basic formulation of our model is not modified by this exchange of roles, although equations (12) and (13) are replaced by the following ones:

$$R = P_m Q - C_p \tag{22}$$

and

$$S = \frac{R - P_f q_f - P_p q_i}{Q} \tag{23}$$

The policy parameter is now the farm price of raw milk (P_m), while the subsidy rate (S) is an endogenous variable. The new formulation is referred to as model II. The conflict matrix of model II is given in table 3.

It is clear that the internal structure of the conflict has been thoroughly altered. In particular, consumers are now completely separated from producers, with the government occupying a central position. Furthermore, while there still exist some tactical differences among producers, they have been narrowed, as both groups are now indifferent with respect to consumer prices. The relative shares of production are still an internal matter of the producers' groups. a graphic presentation of the conflict structure is provided in figure 2.

According to our model, the equilibrium solution is invariant under the two models, since the set F of structural restrictions on the economic variables has not been altered. Nevertheless, there are some tactical differences. Thus, model II appears to be more advantageous to farmers and consumers alike. First, it minimizes internal friction among producer groups, thereby strengthening their coalition, and second, both consumers and producers avoid the confrontation among themselves inherent to model I. The significant fact is that negotiations among the various interest groups have actually conformed to the pattern implied by model II.

Concluding Remarks

In the present study, an attempt has been made to capture the behavioral regularities discernable in a sectoral political economy. To this end, an extended model has been developed and applied embracing the economic relations as well as the political power structure. The underlying theory was a combination of Tinbergen's (1954, 1956) concep-

Table 3. The Conflict Matrix, Model II

Interest Group	Policy Instruments: Consumer Price of Fluid Milk (P_f)	Consumer Price of Other Dairy Products (P_p)	Domestic Production (Q)	Production Share of Kibbutz Farms (k)	Producer Price of Raw Milk (P_m)
Government (u_0)	133,300	275,060	−302.6	0	−286,420
Kibbutz farms (u_1)	0	0	131.8	76,273,000	100,550

tion of quantitative economic policy and the Nash-Harsanyi model of a bargaining game. The study may, therefore, be regarded as an empirical test of the underlying theory. How well, then, did the model fare in this experiment? Admittedly, the explanatory power of the model was not entirely convincing, but, as the analysis has shown, the failure may in

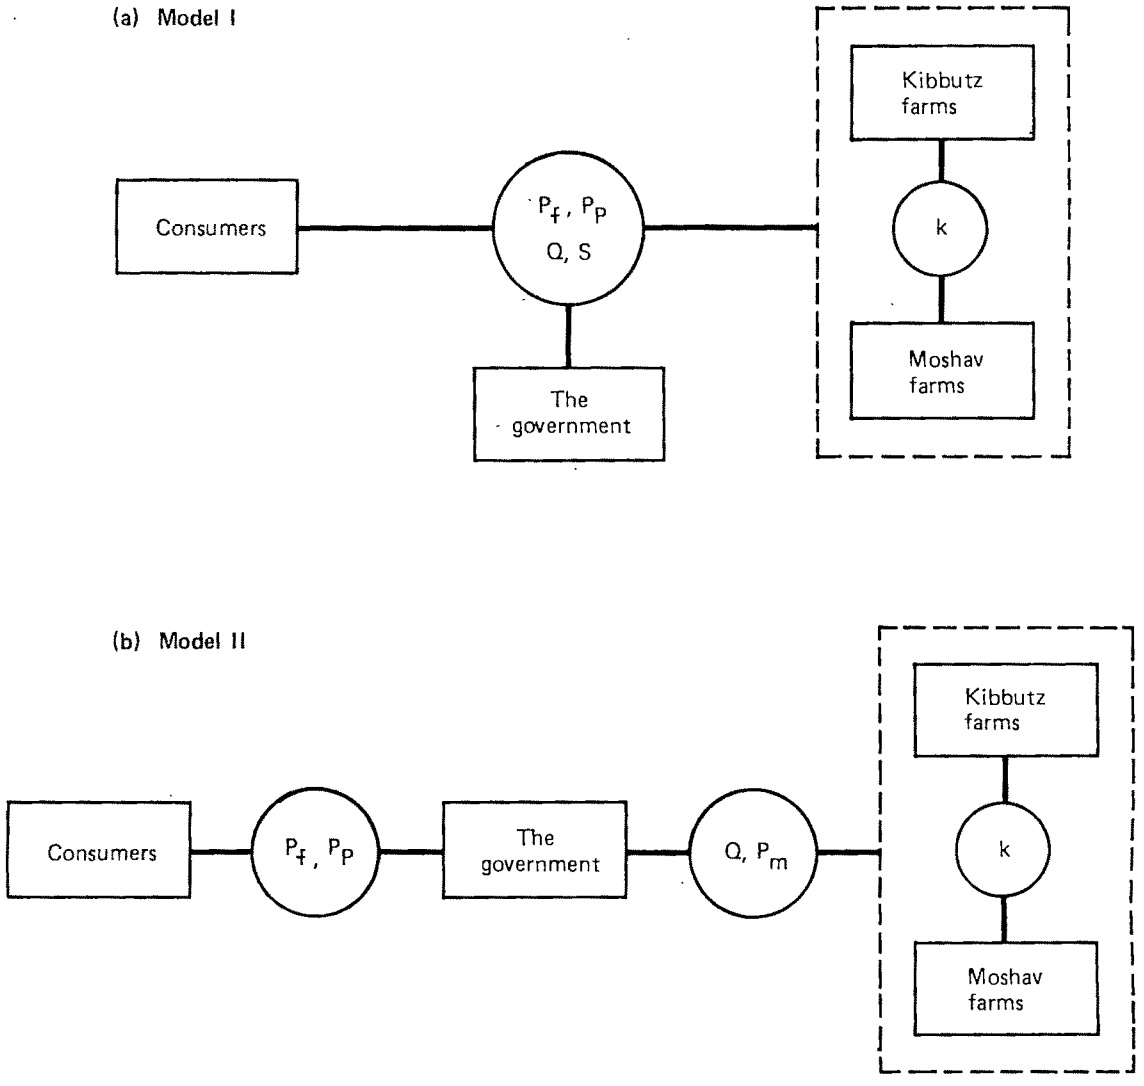

Figure 2. The internal structure of the conflict

effect become a blessing in directing the investigator's attention to necessary revisions in his formulation, shedding additional light on structural and behavioral characteristics of the system. Moreover, it is not unlikely that political-economic systems do involve a strong unexplainable element.

An Evaluation of the Common Agricultural Policy as a Barrier Facing Agricultural Exports to the European Economic Community

Gary P. Sampson and Alexander J. Yeats

The influence of the European Economic Community's Common Agriculture Policy on world agricultural prices and exports of producing nations is analyzed. CAP reduces demand for agricultural imports, imparting more inelasticity into the world demand for them. Increased inelasticity amplifies price fluctuations born by non-EEC producers. Results stress the need for incorporating the subject of agricultural protection into the agenda of the current multilateral trade negotiations. Since CAP can amplify fluctuations in world agricultural prices, the system has a direct detrimental effect on non-EEC producers. CAP's potential for trade restriction, under levies and other protectionist measures, is significant.

Key words: agricultural protectionism, agricultural trade, Common Agricultural Policy, European Economic Community, trade barriers.

For a variety of reasons, nations such as the United States, Canada, and Australia are generally acknowledged to possess natural advantages over the European Economic Community (EEC) in the production of a wide range of agricultural commodities. The EEC, in turn, has competitive advantages in the production of some manufactured and durable goods. Since traditional economic theory leads us to believe that the level of global welfare is maximized when nations produce and trade those items in which they have a comparative advantage, it is in the best interests of agricultural exporting nations and the EEC to facilitate the international exchange of these commodities.

Over the course of the last decade, an issue of steadily increasing controversy has centered on the trade restrictions imposed on agricultural products by the Common Agricultural Policy (CAP) of the EEC. Proponents of this system argue that a primary objective of CAP is internal producer income maintenance and stabilization and, as such, it cannot be considered in trade liberalization negotiations.[1] This view has been bitterly contested by potential exporters of agricultural commodities who have found their products effectively blocked by the EEC's variable levies and other related measures. Adding to the confusion has been the lack of systematic empirical studies aimed at evaluating the magnitude of the trade barriers posed by the system.[2]

Since much relevant data are now available, the trade restrictive effects of CAP need not be left entirely to conjecture. The purpose of this study is to attempt such an

Gary P. Sampson is a senior lecturer in economics, Monash University, Melbourne, Australia, and Alexander J. Yeats is first economics officer in the Research Division, United Nations Conference on Trade and Development, Geneva, Switzerland.

The views expressed in this paper do not necessarily reflect those of the authors' institutions. The authors thank Andrzej Olechowski for comments and suggestions on certain aspects of data preparation.

[1] In both the Kennedy and current Tokyo rounds of multilateral trade negotiations, the EEC has refused to have the issue of the Common Agricultural Policy placed on the formal agenda. This action has been taken in the face of strong protests from agricultural-exporting nations.

[2] Using Sweden, which also makes use of variable levies, as a case study, Sampson and Yeats demonstrated that the trade barriers posed by MFN tariffs may be insignificant in comparison to the restrictive effect of levies (1976a). In addition, Wipf has made some estimates of the *ad valorem* incidence of the EEC's variable levies and noted that many were over 50% and even reached 300% in the case of butter.

evaluation. While the frequency with which all known nontariff barriers are applied by the EEC is analyzed, this investigation places particular emphasis on variable levies. We concentrate on levies since these special import charges form the cornerstone of the Common Agricultural Policy and are among the most widely used measures to control agricultural imports. Levies are given special attention also since data are now available for empirically assessing their importance through estimation of tariff equivalents.

This paper proceeds in three parts. First, we discuss the main features of the Common Agricultural Policy and show how variable levies are used to control the flow of imports. The importance of levies as a trade barrier is demonstrated through comparisons of their *ad valorem* incidence on agricultural products with that of current most favored nation (MFN) tariffs. In making these comparisons, we draw heavily on the effective protection concept to show how these measures influence the protection for value added in a production process.[3] After this analysis is an evaluation of the other protectionist measures (i.e., quotas, minimum import price schemes, state trading, etc.) employed by the EEC. While the exposition here is largely descriptive due to problems in quantifying the effects of these restraints, clearly these measures are important supplementary devices (to levies) for restricting agricultural trade. The paper closes with an overall evaluation of the Common Agricultural Policy and its impact on agricultural-exporting nations.

The Common Agricultural Policy: An Overview

The EEC's treaty of Rome created the Common Agricultural Policy as a vehicle for achieving the specific objectives set forth in Articles 38–40: to create a common market in agricultural products, increase agricultural efficiency, provide a fair standard of living for the agricultural community, stabilize markets, ensure security of supply, maintain reasonable prices for consumers, and develop world trade harmoniously (Commission of the European Communities). To achieve these ends, an intricate system of protectionist devices and production aids has evolved over the last decade. This system, which now covers more than 90% of total EEC agricultural output, involves a mass of market regulations, including schemes for internal price support, external protection measures (e.g., tariffs and levies) and production subsidies.[4] However, it should be kept in mind that none of these measures need to operate independently. For example, the degree of external protection required to keep domestic prices competitive with world prices varies inversely with the support provided by production subsidies.[5]

While regulations differ according to commodities, the basic philosophy of the Common Agricultural Policy regarding internal price support and external protection has evolved out of the 1962 regulations for the marketing of grains.[6] The three key elements of this program are as follows.

(*a*) A basic target price (P_t) is established each year in advance of the following crop year. This price is intended to serve as a guide for producers in allotting future acreage. Since transportation charges will influence price differentials within the EEC, the target price is set as the delivered (cost,

[3] Essentially, effective protection measures the percentage change in value added from free trade levels that is permitted by the structure of a country's tariffs and other protectionist measures. For basic references on the topic, see Corden or Grubel. Economists have generally been reluctant to apply the effective rate concept to agricultural products due to a previous lack of empirical information on the incidence of nontariff barriers to trade, such as levies. The new data sources on *ad valorem* rates for these charges rectify much of this deficiency. Recent studies have demonstrated that problems in estimation of production coefficients, or substitution among factors of production, may bias effective protection estimates (see, for example, Sampson 1974 or Yeats 1976). Since both these factors may influence the estimates shown in this analysis, they should be regarded with some caution.

[4] For example, 72% of agricultural production is covered by price support schemes plus external protection, while 25% of total output has exclusively external protection. In general, price-support programs have been applied to products in which the EEC wishes to maintain self-sufficiency. Finally, supplementary production aid covers 2.5% of production, and aid at a fixed rate per hectare accounts for 0.6% (see Commission of the European Communities, p. 12).

[5] Specifically, production subsidies permitted the domestic price of olive oil to fall to 64% of the producer price over 1967–72. In this situation, external protection was lower than would have been required in the absence of this support. High production subsidies on olive oil result in reduced demand for other products, i.e., peanut oil, coconut oil, etc., that have a high cross elasticity of demand.

[6] Grains are of central importance to the EEC, accounting for half of the total cropland. Also, as a major input into the production of some commodities, their price is an important factor influencing the required level of protection in other sectors. For a more detailed discussion of the grains price support program, see UNCTAD (1967) or OECD.

insurance and freight) price in Duisberg, Germany.[7]

(*b*) An intervention price (P_i) is the price guaranteed to producers. More than 400 intervention and marketing centers have been established throughout the EEC and stand ready to accept all quantities of cereals offered at this floor price. While there is variation on a product by product basis, the intervention price is generally not more than 10% below the target price.

(*c*) Threshold prices (P_h) are used to insulate domestic EEC prices from fluctuations in world price (P_w) levels. The threshold price is equal to the basic target price minus transport costs from a fixed port of entry to the center of largest deficit. Imports from non-EEC countries are then subject to a variable levy that equals the excess of the threshold price over the world price.

The interconnections between these various prices and the functioning of the levy system can best be expressed in symbolic form. In equation (1) below, the target price is established at a certain fixed level k. Equation (2) shows the relation between the intervention price and the target price, while equation (3) indicates that the threshold price is equal to the target price minus internal (EEC) transport charges. The key to this system, equation (4), shows that the variable levy fluctuates to maintain equality between world and domestic EEC prices.

$$P_t = k, \tag{1}$$

$$(P_i - 0.1P_t) \leq P_i \leq P_t, \tag{2}$$

$$P_h \equiv P_t - T_d \tag{3}$$

and

$$L_i \equiv P_t - (P_w + T_d), \tag{4}$$

where $L_i \lesseqgtr 0$.

Evaluation of the relationship shown in equation (4) indicates how the variable levies operate to restrict demand for foreign agricultural products. By incorporating a variable charge (L_i) into the delivered price of imports, the system maintains foreign prices at or above those received by domestic producers. When levies are positive they hold demand for imported agricultural products below levels that would prevail in their absence.

While the above demonstrates that variable levies restrain import demand, these charges also have an adverse, destabilizing effect on natural fluctuations in world agricultural prices. Thus, while the Common Agricultural Policy serves to insure stability for domestic producers, it does so by augmenting the instability in prices born by foreign producers by increasing the inelasticity of world demand curves.

Variable Levies: An Empirical Assessment

A point that follows from the previous analysis is that the trade effects of variable levies are related to the ratio P_t/P_w. Thus, the higher the EEC target price is above world levels, the greater the *ad valorem* incidence of levies on imports, and the larger the curtailment of potential import demand.

For information on these *ad valorem* rates, a General Agreement on Tariffs and Trade document is used. Essentially, this study approximates nominal rates for the variable levies (N_L) by tabulating revenues from these charges as a percentage of the total value of imports:

$$N_L = \sum L_i Q_i / \sum P_i Q_i, \tag{5}$$

where P_i and Q_i are prices and quantities of six-digit Brussels Tariff Nomenclature (BTN) items imported into the EEC over the period 1969–70.[8] In general, these ratios are computed for each six-digit BTN item to which a levy is applied. However, in some cases these import charges are apparently set at levels sufficient to restrict trade ($\sum P_i Q_i = 0$), with the result that an *ad valorem* incidence cannot be estimated.

Table 1 illustrates the importance of variable levies for products classified in SITC 0 (food and live animals) and SITC 4 (animal and vegetable oils). Shown here is the per-

[7] Duisberg was selected since it represents the greatest grain deficit (i.e., production minus consumption) region in the EEC.

[8] Since imports from overseas departments of the EEC member states, from the overseas territories associated with the EEC, and from associated African and Malagasy states are included in the denominator, there is reason to believe that the estimated *ad valorem* incidence is biased downward. Imports from these sources are normally admitted levy free, but apparently they could not be broken out from the six-digit BTN figures.

Table 1. Nominal Protection for EEC Agricultural Products and 1974 Value of Australian Exports

Product Description	SITC	EEC Coverage by Levies		Nominal Protection (%)			Australian Exports ($ million)	
		Tariff Lines	Value of Trade ($ million)	Tariffs	Levies	Total	EEC	World
Food and live animals	0							
Food and live animals	00	33.4	1,828	11.8	18.2	30.0	228	42,059

[a] Australian exports to the EEC were less than $1 million.

centage of trade in each two-digit Standard International Trade Classification (SITC) group covered by levies, as well as similar information on the tariff lines subject to these special charges.[9] For purposes of comparison, we have estimated both the average *ad valorem* tariff and levy rate for these groups and have also computed their joint protective effect. Finally, to assist in evaluating the influence of these charges on one important agricultural exporting nation, we have tabulated Australian exports of these products to the EEC as well as to all other destinations.

Perhaps the most striking feature in table 1 concerns the relative height of the average nominal tariff and average *ad valorem* equivalent of the variable levies. In SITC 0, for example, a nominal tariff rate of 18% is coupled with levies whose average rate is approximately three times this figure. Only in the case of SITC 06 (coffee, tea, cocoa, and spices) is the incidence of the variable levies less than that for tariffs. The primary reason for this departure is a tariff rate that averages over 50%. Much the same picture concerning the relative importance of these import charges can be observed in SITC 4 (animal and vegetable oils), where average tariffs of approximately 8% are coupled with levies of 24%.[10] On an overall basis, these groups enjoy protection of over 60% from tariffs and levies, with roughly two-thirds of the total from levies.

A product-by-product comparison shows the total nominal rates of protection facing a large proportion of these agricultural products are extremely high. For example, when levies are combined with tariffs, the nominal rate for dairy products and eggs is over 170%. Cereals and preparations face a combined trade barrier of almost 70%, while nominal rates of protection for meat and sugar are both about 50%. The impact of these charges can be appreciated by noting that they reduce the EEC's share of Australian exports

[9] The tariff line is the most disaggregate level of product detail used for classifying imports and is employed for determining applicable tariffs and other trade restrictions.

[10] While the value of the variable levy may be changed frequently, published estimates of their incidence over the period 1967–71 indicate that the figures shown in table 1 are generally representative of their longer-term levels. For some products, however, they may be low. For example, during 1968–69 and 1969–70, the *ad valorem* incidence of the levies was over 500% on butter while that for sugar ranged from 110% to 330% (see UNCTAD 1972). There are a number of other agricultural or related products falling in SITC 2 (crude materials). However, the incidence of tariffs and nontariff barriers (NTB's) on these items are not analyzed due to the large number of two-digit component products that are distinctly nonagricultural in nature (i.e., fertilizers, metal ores, etc.).

to less than 10% for these key products, while the share of these items in the value of exports constitutes 40% of the Australian total.

While the beverage and tobacco group is not subject to levies, protection from tariffs has been substituted. For example, tobacco manufacturers face an average tariff rate of over 60%, while a nominal rate of 27% is applied to beverages. In assessing this latter figure, it should be noted that transportation costs for such items may constitute a high percentage of product price.[11] Thus, tariff protection for bulky, low-value products need not be set as high as that for other products, since transportation costs provide a natural trade barrier. The overall impression that emerges from table 1 is that artificial protectionist measures such as tariffs and levies have been set at very high levels and constitute an imposing barrier to trade in agricultural products.

Effective Protection of Agricultural Products

While the previous analysis provided an overview of the coverage and importance of variable levies, it told nothing about the influence of these charges on the protection of value added (the effective rate) in a production process.[12] Yet the protection of value added is of key importance, since this indicates the extent to which foreign producers must operate with direct costs lower than their EEC counterparts in order to penetrate this market.[13]

Information required for the estimation of effective protection rates was drawn from data compiled in the United Nations Conference on Trade and Development (UNCTAD) secretariat in connection with preparations for the Tokyo round of tariff negotiations. Essentially, the data required for the estimation of the required production process input shares come from national input-output tables, although in some cases this information was supplied by Food and Agricultural Organization experts (through correspondence).[14] This data was employed, with information on the EEC's tariffs and variable levies, to estimate the effective protection stemming from each of these charges on imports.[15]

Table 2 shows the estimated effective protection rates for these agricultural products and also indicates nominal rates of protection. To assist in evaluating these results, effective protection estimates derived separately from tariffs and levies are given as well as that for their combined effect. Finally, the table shows average nominal and effective rates for these products.

Perhaps the most interesting feature in table 2 concerns the relative importance of tariffs and levies as sources of protection against imports. For the nine farm gate products, an average tariff rate of 14% already presents an imposing trade barrier, yet the additional nominal protection from levies (45%) is roughly three times this figure. Much the same pattern is observed for the processed agricultural products as an average tariff rate of 18% is combined with a nominal rate for levies of 75%. Only in one case out of the twenty-three products with joint coverage (meal and groats) is the nominal tariff rate larger. Altogether, the evidence from these comparisons suggests that variable levies are a far more important source of protection for agricultural products then current MFN tariffs.

[11] For example, Sampson and Yeats (1976b) found that the average 1974 *ad valorem* incidence of transport costs for Australia's beverage exports to the United States was roughly 30%. Fruit and vegetables had an *ad valorem* rate of 38%, while meat and dairy products had rates of 13% and 15% respectively. While this study concentrates on penetration costs for the U.S. market, evidence is presented to show that the transport rates should be roughly the same for the EEC.

[12] The effective rate of protection E_j for a product j is normally defined as

$$E_j = (V_j' - V_j)/V_j, \tag{6}$$

where V_j is the value added coefficient in a free trade situation and V_j' is this share under protection. Effective rates differ from nominal rates in that the latter only measures protection for the final product, while the former measures the protection for value added in a production process.

[13] For example, the effective rate of protection in a production process with a free trade value added coefficient of 40%, and nominal tariffs of 20% and 10% on the end product and material inputs, is 35%. In order to sell in such a protected market, foreign producers would have to operate with a remuneration of productive factors 26% below that in the protected market.

[14] For a detailed discussion of how the input coefficients are estimated, as well as a discussion of other aspects of this study, see Yeats (1974).

[15] If r_i and η are the *ad valorem* equivalents of variable levies on material inputs and the final product, while t_i and t_j are the nominal tariffs on these items, then the effective rate of protection from both elements is

$$E_j = ((t_j + \eta) + \Sigma\, a_{ij}(t_i + r_i))/V_j, \tag{7}$$

where a_{ij} is the free trade share of production input i. Obviously, the effective rate of protection by tariffs and levies combined is the sum of the effective rate from each element.

Table 2. Comparison of Nominal and Effective Rates of Protection for Selected Agricultural Products in the EEC

Description	Nominal Rate (%)		Effective Rate (%)		
	Tariffs	Levies	Tariffs	Levies	Total
Farm gate products					
Oats	13.0	84.2	25.8	177.9	203.7
Rye	16.0	75.8	32.1	160.0	192.1

Groundnut oil	7.5	—	92.9	—	92.9
Coconut oil	8.0	—	70.3	—	70.3
Average	18.2	56.1	49.3	134.1	158.1

Note: The average values shown for the variable levies exclude those products not covered by these special import charges.
[a] Variable levies are not applied to this product group.

Similar conclusions concerning the relative importance of tariffs and levies emerge from comparisons of the effective protection estimates. For the farm gate products, an average effective tariff rate of 30% is coupled with effective protection of 63% from levies. However, in the case of livestock, variable levies on grains and other basic feeds raise producer costs and reduce effective protection below corresponding levels for tariffs.[16] A similar pattern emerges for some of the processed grain products (i.e., meal and groats, puffed cereals, etc.) where levies on the basic input artificially inflate production costs.

[16] A number of other nontariff trade restraints are applied to these items, and their influence may offset the reduced effective protection from levies. For example, sheep imports are subject to quotas, special licensing restrictions (France), and minimum import price restrictions.

On an overall basis, effective protection from levies averages 134%, roughly two-and-a-half times the effective tariff rate. However, certain key products—meat, cereals, fruits, and vegetables—face an average effective protection rate of 150% or more, with the major portion of this protection associated with variable levies. Undoubtedly, protection set at these levels is a primary reason why Australia's exports to the EEC have been held to the low levels indicated in table 1.

Application of Other Nontariff Restraints

While the preceding sections empirically evaluated the trade barriers posed by the

EEC's tariffs and variable levies, there is a variety of other nontariff trade restrictions applied to agricultural imports by the community. Unfortunately, it is difficult to quantitatively assess the influence of these measures since *ad valorem* equivalents have not yet been calculated. However, a tabulation of their frequency of use and products to which they are applied is helpful in providing an indication as to their importance as obstacles to international trade.

Using information drawn primarily from UNCTAD's multilateral trade negotiation data base,[17] table 3 shows the types of nontariff restraints applied to various agricultural products. The impression that emerges from this inventory is that an extensive and complex system of controls has been established to effectively regulate or limit foreign competition for domestic producers. While variable levies are applied to fourteen of these three-digit product groups, the table indicates that quotas or other quantitative restrictions are used with almost equal frequency. Table 3 also shows that special licensing arrangements are used for controlling imports of nine of the three-digit products, while state trading is employed for regulating imports of certain meat and cereal products. The most prevalent type of trade obstacle agricultural-exporting nations face are special preferences for associated countries. Since these measures reduce the MFN tariffs (or levies) for beneficiaries, they do much to offset the comparative advantages that countries like Australia, Canada, or the United States have in the production of some of these products.

[17] This data bank has been prepared to assist less developed countries in evaluating the number and types of NTB's applied to their exports by industrial countries. For references concerning the construction of and output from this project, see UNCTAD (1973, pp. 36–39).

Conclusions

This paper analyzed the influence of the Common Agricultural Policy on agricultural

Table 3. Nontariff Trade Barriers Facing Agricultural Exports to the EEC

Description	SITC	Nontariff Trade Restraint[a]
Live animals	001	PHS, R, SP

[a] Restrictions applied in whole or in part to the SITC group. The key to these symbols is as follows: PHS, HS = prohibitions due to health and sanitary reasons, or health and sanitary regulations; SP = special import preferences for states associated with the EEC; Q = quotas (method unspecified) or bilateral quotas; GQ = global quota; DL, LL = discretionary licensing or liberal licensing of imports; L = import licensing (method unspecified); VL, MP = variable levy or other minimum import price restrictions; R, SP = restrictions (method unspecified) or special seasonal restrictions; and ST = state trading.

prices and exports of producing nations. After specification of a simple algebraic model to illustrate the operation of the system, it was demonstrated that the Common Agricultural Policy has the capacity to reduce demand for agricultural imports. The system also imparts a greater degree of inelasticity into the demand curve for these items. The effect of the increased inelasticity is to amplify price fluctuations borne by foreign (non-EEC) producers. This induced price instability is quite apart from the disruptions in world markets caused by the disposal of agricultural surpluses that occasionally build up under the Common Agricultural Policy. Thus, while proponents of the system may argue that the Common Agricultural Policy is a vehicle for achieving domestic price stability, this is undoubtedly accomplished by reducing imports and transferring instability to foreign producers.

To assist in evaluating the trade restrictive nature of the Common Agricultural Policy, the *ad valorem* incidence of the EEC's variable levies are computed. When these figures are compared for a variety of agricultural imports (table 1), the restrictive effect of the levies is seen to be more than double that of current MFN tariffs on these items (44% versus 20%). however, for some important products, i.e., dairy products, cereals, etc., the *ad valorem* incidence of the variable levies is considerably higher. When viewed within the framework of the effective protection model, the trade barriers posed by the Common Agricultural Policy are found to be even more imposing. Furthermore, the analysis indicates that there are a number of other important trade barriers applied to agricultural imports by the EEC, although the exact magnitude of their influence could not be quantified.

For several reasons, the results contradict the argument that the Common Agricultural Policy is solely an income maintenance and stabilization program and therefore not subject to trade liberalization negotiations. Since the Common Agricultural Policy can amplify fluctuations in world agricultural prices, the system has a direct detrimental effect on non-EEC producers. Also, the Common Agricultural Policy's potential for trade restriction, under levies and a variety of other protectionist measures, are indeed significant. No inherent reason exists why these trade control measures should be treated differently within the context of the current multilateral trade negotiations from those measures applied in the nonagricultural sector.

Agricultural Sector Models and Their Interface with the General Economy (Karl A. Fox, Iowa State University, Chairman)

The Wharton Agricultural Model: Structure, Specification, and Some Simulation Results

Dean T. Chen

Econometric analysis is sometimes criticized because it has failed to make a substantial contribution to forecasting and policy formulation in agriculture. We are told of the various avenues by which improvement in agricultural forecasts can be made through the use of econometric models. A primary conclusion drawn by speakers at the 1976 AAEA annual meeting points to the need for a large-scale, integrated agricultural sector model for on-going and on-line use. The need for an improved forecasting system to encounter massive recent changes in agriculture was suggested by Fox (1973), who found us ill prepared in terms of data, models, and analytical procedures for the tasks of forecasting and policy formation. A study of several well-known macroeconometric models by Popkin further supports this view because almost two-thirds of the average prediction error of econometric inflation forecasts in recent years could be traced to the changes in exogenous prices, among which the farm and food prices are the key components.

Improvements of agricultural price forecasts were initially suggested within the context of a macromodel itself, e.g., by adding a number of behavioral equations and restructuring the price transmission mechanism. However, because of the gap existing between the complexities of farm commodity markets and the simplified nature of the agricultural sector specification in macromodels, little can be expected from such an enhancement. An integrated view of the agricultural economy in general and market behavior of individual commodities in particular is needed. Capturing the interdependence and providing coordination can be greatly facilitated by considering a full-size, multipurpose agricultural sector model. Work in this direction has several precedents (e.g., Fox 1965, Cromarty, Evans), but none of these models have actually been used in applied work; therefore, a fresh start is needed.

Agricultural economists have constructed an impressive number of econometric models at the commodity level (see Labys or King). Scattered attempts at commodity models have been poorly integrated with national or agricultural forecasting systems, severely limiting their uses in practical work. This leads to the so-called traditional paradox of "meaningful parts forming meaningless whole" in agricultural model research (Tweeten, p. 181). A lack of comprehensive and sustained effort was cited as a key deterrent to agricultural econometric forecasting. The most neglected aspect of model research is on forecasting evaluation, which is the best means for pinpointing biases and for improving forecast performance. If structural estimation, theory testing, and prediction are integral parts of one larger econometric problem (Klein 1971a), model building and especially forecasting application should re-

---

The papers in the "Proceedings" section were presented at the fall meeting of the AAEA held in conjunction with the Allied Social Sciences Association in Atlantic City, 16–18 September 1976.

The author's greatest debt is to Lawrence R. Klein for his encouragement and guidance and to Kenneth R. Farrell for his friendly interest and support. The author also wishes to thank Gerard F. Adams, George R. Schink of Wharton Econometric Forecasting Associates, Richard C. Haidacher, Terry Barr, Charles E. Overton of the U.S. Department of Agriculture, and William A. Cromarty and Walter Myers of the Connell Rice & Sugar Company for the help given to this study. Capable and dedicated research assistance by Selig L. Sechzer is gratefully acknowledged.

ceive more attention by agricultural economists.

Objectives and Approach

For any model-building work, careful consideration must be given to two conceptually different but practically related methodological issues: modeling applications and the modeling process. Given the current state of knowledge and analytical needs, the model builder's attention should be directed not only toward the "true" economic structural relations as a close approximation to economic reality but also to the design of a reliable and sensible tool for practical uses. In pursuit of this goal, the model presented in this paper has been constructed.

The design of the Wharton Agricultural Model reflects its purposes. (*a*) As a short-term econometric forecasting model, it is useful for quarterly forecasts of supply, demand, and prices of individual farm commodities and for the determination of farm income and expenditure flows. (*b*) As a simulation instrument, the impacts of alternative conditions of weather, government farm programs, farm commodity export and world crop production, and macroeconomic policy can be analyzed. (*c*) As an analytical tool, it can be used for sensitivity analysis of the market adjustment mechanism, the interactions among the farm and nonfarm sectors, and the international linkages between U.S. and foreign agriculture.

A useful model should be constructed on a quarterly basis with a great degree of commodity detail.[1] A quarterly model is favored over an annual model because decision making in agriculture has been influenced by short-term agricultural developments, e.g., seasonal crop development, livestock numbers on farm, and rapid fluctuations of export demand conditions. A systematic and rigorous analysis of quarterly data could contribute greatly to forecasting efficiency and policy precision. Proponents of intertemporal disaggregation suggest that such a model would have the least bias, the least simultaneity in the system of economic relationships, and the least specification error concerning causal directions and, at the same time, might not give rise to greater serial correlations in disturbance terms (e.g., Liu and Hwa).

When one considers the gap between what econometric models forecast and what business users need to forecast, the choice of the larger, more complex model is inevitable. Business leaders have long been dissatisfied with the divergent development of the "theoretical model" and the "user model" (Crowder, Cromarty and Myers). This phenomenon is indeed a serious one, but there is a tendency to a gradual narrowing of this gap. After all, other than for the advancement of economic theory and econometric methodology, econometric models are constructed for the purpose of practical application. Unquestionably, there must be common ground in terms of problem orientation and technical orientation guiding model-building work in agriculture.

The limitations of large simultaneous equation systems as summarized by Cromarty and Myers are difficulty in adjusting to structural changes, rigidity imposed by internal consistency, the management of a large, complex information system, and the inability to predict exogenous variables that are specified as endogenous variables in larger models. However, given existing computer technology and econometric techniques, some of these difficulties are being overcome. The size and complexity appears to be less of a methodological issue nowadays because, as long as a model can be constructed and maintained economically and effectively, there should be little objection to bigness. In order to gain insight and flexibility, any part of a large model actually can be isolated and run as a separate entity. For this reason, a large model may have the advantages of both largeness and smallness especially with a multicommodity framework. The Wharton macromodel experience indicates a historical trend toward bigness. User requirements and the advantage of spreading risks all push toward the development of larger models (Klein 1971b).

Another consideration important to modeling applications is related to data. A useful model must be so constructed to follow a schedule closely tied to the quarterly release of economic data by government statistical agencies. As data are obtained from original sources and updated quickly and reliably, there is need to choose the right data series

[1] As a comparison to other models, Cromarty's and Evans's are annual models, while the FOX-SSRC Brookings is a quarterly model but lacks commodity details.

for the right variables. A basic strategy is to develop the model with sufficient points of contact with the U.S. Department of Agriculture information system, especially those of the Crop and Livestock Reporting Board, the Outlook and Situation Board, and the newly implemented Computerized Outlook Information Network (COIN).

The Overall Model Structure

The Wharton Agricultural Model can best be described by considering it to be subdivided into four blocks of equations: the intercommodity block, the annual crop production block, the income-expenditure block, and the micro-macro linkage block.

Among the four interrelated blocks, the intercommodity block is undoubtedly the heart of the model, containing simultaneously determined quarterly equations of supply, demand, inventory, and price relations for seventeen commodities or commodity groups. For the livestock sectors, the model provides detailed information of animals on feed, commercial production, per capita retail demand, and prices received by farmers for six commodities: cattle and calves, hogs, dairy, broilers, turkeys, and eggs. The information to be forecast for the crop sectors includes stocks on and off farm, domestic utilization (for feed, food and industry, and seed), export sale, and average prices received by farmers. The model covers eleven major crops: food grains (wheat, rice, and rye), feed grains (corn, sorghum grains, oats, and barley), soybeans (soybean oil and soybean meal), cotton, tobacco, vegetables, and fruits.

The actual and prospective changes in annual crop production have often played a pivotal role in the short-term development in agriculture. Moreover, projections of annual crop production are a starting point for any meaningful analysis of changes in government farm programs as well as current weather development. The annual crop production block is thus not only an important forecasting device for a timely evaluation of the prospects for each crop but also is useful for impact simulations. In formulating production response, two behavioral equations (planted acreage and yield per harvest acre) and an identity for total crop production are generally needed. To complete the crop production identity, an important exogenous variable, the harvested acreage as a percentage of planted acreage, must be included. This variable is used as a proxy variable for weather impact study if it can be explained by actual weather data such as rainfall and temperature. Unlike the intercommodity block, which contains quarterly and simultaneous equations, this block is annual and recursive.

The income-expenditure block provides the main statistical identities relating the income and expenditure accounts for the agricultural sector of the U.S. economy. For farm income components, the relationships are basically definitional, reflecting the standard concepts and procedures in the derivation of cash receipts from farm marketings, realized gross farm income, realized net farm income, and total net farm income. Since the intercommodity block provides information about prices and volume of farm supply of individual commodities, such information can be used to generate cash receipts from farm marketings, both in total and by commodity. Given farm cash receipts, the realized gross farm income can be derived by adding the nonmoney income and government payments. The realized net farm income is the difference between realized gross farm and farm production expenses, while the total net farm income is the sum of realized net farm income and the net changes in farm inventory. A two-step procedure was employed to determine the equation for farm prices paid, which in turn is used to determine the farm production expenses equation. In addition, the net changes in farm inventories are also treated as an endogenous variable to reflect the stages of farm commodity cycles and inventory adjustment mechanism in business cycles.

The micro-macro linkage block provides a set of bridge equations to treat the agricultural sector in similar form and specification as other production sectors of the economy by focusing on aggregate demand components, output origination, wage, labor and employment, sector prices and final demand prices, farm income, and personal income components. With the completion of the linkage block, a full feedback relationship between the agricultural sector and the macromodel can be expected. It also allows for testing the agricultural implications of macroforecasts and macroimplications of agricultural forecasts.

Simplified Specification of the Model

I now review briefly the issues concerning the modeling process: specification, estimation, and simulation. As the surveys by Labys and by King indicate, commodity model builders have encountered a host of problems and difficulties in recent years. Most notable are the specification problems due to the omission of monetary and speculative factors, the failure to link the model in a multicommodity framework, the difficulty in modeling climatic conditions, the inability to measure export demand fluctuations, and the weakness in the analysis of inventory and price dynamics.

In developing a model, it is important to evaluate each of the problem areas mentioned above and to design strategies for possible improvements. In essence, agricultural markets are characterized by uncertainty in weather and export demand conditions, by lagged responses to price changes, and by nonlinear supply and demand relations. These attributes of uncertainty, dynamics, and nonlinearities form the basic theoretical foundation for improvements of the model. In this study, the effects of weather on crop production were modeled by a multistage impact analysis of acreage, yield, and production through the entire planting, growing, and harvesting seasons. The weather impact analysis was also considered as a direct argument in the price determination equation by using nonlinear probability variables of crop forecast revision. A novel feature involves the development of an internal dynamic system that describes a complex set of interrelated adjustment processes in the feed-livestock economy. A low-order polynomial lag formulation was employed to investigate the lag response pattern of livestock on feed, as well as the demand for feedgrains and soybean meal relations. The nonlinearities were included in both export demand and price equations, helping to track the recent gyrations of these variables. Broadly speaking, the model is structured around the traditional microeconomics framework to determine supply-demand balances and complementary and substitution relations of individual commodities and group of commodities.

In the simplified specification shown in table 1, the agricultural sector of the U.S. economy is represented by twenty-two structural relations in three major equation blocks.[2] A brief comment of the special features of the model is in order.

Equations (1) through (5) describe the feed-livestock complex, including the complete livestock model and the demand for feed component for crops. This specification is designed to take explicit account of the feed-livestock interdependency. Reflecting a complex set of interrelated adjustment processes, the model provides a mechanism to link changes in relative prices to livestock supply as well as demand for feed functions. This adjustment mechanism involves four responses—(*a*) the response of potential output due to producers' adjustment of feeding and hatchery operations: the time path of adjustment varies among commodities, and a flexible lag structure of low-order polynomial was adopted because it showed promising results in another study (Chen, Courtney, and Schmitz); (*b*) the response of actual output due to changes in expectations and adjustments of marketing plans: as producers' marketing decisions are constrained by anticipated net revenue flow, negative supply response to price is expected in the short run (Jarvis); (*c*) the effect of derived demand for feedgrains and soybean meal: the adjustment intensifies by livestock on feed as well as rate of feeding; (*d*) the influence of changes in livestock output and feed consumption on prices for these products: generation and successive generation of this internal dynamic adjustment process help determine the relevant endogenous variables in the system.

Weather impact analysis constitutes a challenging methodological issue in agriculture. Since reliable weather forecasts are currently not available for more than a few days ahead, the best a serious forecaster can do is to evaluate current weather information to determine the size of crops. While such an approach is useful, the result may not be very different from the official USDA estimates or private forecasts. From an econometric modeling point of view, the task is to analyze weather impact on market conditions, especially on price development. A basic advantage of this approach is that when extreme weather conditions occur, we can spot, identify, and analyze their significance for forecasting and policy purposes.

[2] In early stage of model development, the micro-macro linkage equations are taken from the current version of the MARK IV Wharton quarterly model.

Table 1. Simplified Specification of the Wharton Agricultural Model

I. Intercommodity block (quarterly and simultaneous)

Livestock sector

(1) Supply response for feeding and hatchery operations

$$LVKSF_i\text{: } \sum_{L=0}^{K} \alpha_L \left[\frac{LVKPF_i}{\dfrac{\sum_{j=1}^{4} CRPPF_j \cdot CRPDF_j}{\sum_{j=1}^{4} CRPDF_j}} \right]_{-L}, S_d, Z_{1i}$$

(2) Farm supply function

$$LVKAP_i\text{: } \frac{LVKPF_i}{\dfrac{\sum_{j=1}^{4} CRPPF_j \cdot CRPDF_j}{\sum_{j=1}^{4} CRPDF_j}}, LVKSF_i, S_d, Z_{2i}$$

(3) Retail demand function

$$LVKPF_i\text{: } \frac{LVKRD_i}{TCPOP}, \frac{RDPI}{TCPOP}, LVKPF_s, RCLVK, S_d, Z_{3i}\ (s \neq i)$$

(4) Supply-utilization balance (identity)

$$LVKRD_i = LVKAP_i \cdot W_i - LVKMX_i + LVKMI_i + \Delta LVKHT_i$$

Subscripts i and j above stand for commodity disaggregations for livestock and crops, where $i = 1, \ldots, 6$ for cattle, hogs, dairy, broiler, turkey, and eggs and $j = 1, \ldots, 4$ for corn, sorghum grains, oats, and barley.

Crop sector

(5) Demand for feed

$$\frac{CRPDF_j}{\sum_{i=1}^{6} \delta_i \cdot LVKSF_i}\text{: } \sum_{L=0}^{N} \beta_L \left[\frac{CRPPF_j}{\dfrac{\sum_{i=1}^{6} LVKPF_i \cdot \delta_i \cdot LVKSF_i}{\sum_{i=1}^{6} \delta_i \cdot LVKSF_i}} \right]_{-L}, \left[\frac{SOMPM44DE}{\dfrac{\sum_{i=1}^{6} LVKPF_i \cdot \delta_i \cdot LVKSF_i}{\sum_{i=1}^{6} \delta_i \cdot LVKSF_i}} \right], \frac{CRPPF_j}{CRPPF_s}, S_d, X_{5j}\ (s \neq j)$$

where $j = 1, \ldots, 7$ for corn, sorgnum grains, oats, barley, wheat, rye, and soybean meal.

(6) Demand for food and industry

$$\frac{CRPDH}{TCPOP}\text{: } \frac{CRPPF}{PDCENF}, \frac{RDPI}{TCPOP}, \frac{.WRHBP}{PDCENF}, S_d, X_6$$

The subscript j, denoting the individual crop sectors, is omitted. The cross-commodity specification described by equations (6) through (14) cover, if data are available, a total of nine crops in the present version of the model: wheat, rice, rye, corn, sorghum grains, oats, barley, soybeans (soybean oil and soybean meal), and cotton.

(7) Demand for seed

$$CRPDS\text{: } CRPSA, CRPSP/DS, \frac{CRPPF}{CRPEU}, X_7$$

(8) Export demand function

$$CRPMX\text{: } \frac{CRPPF}{DEV}, \frac{CRPPF_j}{CRPPF_s}, \frac{GDPW}{POP}, STK/L4M4 \cdot MIN, SPW/USM4 \cdot MIN, Sd, X_8\ (s \neq j)$$

Two of the nonlinear variables, $STK/L4M4 \cdot MIN$ and $SPW/USM4 \cdot MIN$ in equation (8) are

$$STK/L4M4 \cdot MIN = \left(\frac{1}{4} \sum_{i=0}^{3} \left(\frac{STK}{STK_{-4}} \right)_{t-4} - MIN \frac{1}{4} \sum_{i=0}^{3} \left(\frac{STK}{STK_{-4}} \right)_{t-i} + 0.1 \right)^{-1}$$

and

$$SPW/USM4 \cdot MIN = \left(\frac{1}{4} \sum_{i=0}^{3} \left(\frac{PROW/POP}{CRPSP/TCPOP} \right)_{t-1} - MIN \frac{1}{4} \sum_{i=0}^{3} \left(\frac{PROW/POP}{CRPSP/TCPOP} \right)_{t-1} + 0.1 \right)^{-1}$$

Table 1. Continued

(9) Price determination

$$CRPPF\text{: } CRPHT/DT\cdot MIN,\ \frac{1}{4}\sum_{t=0}^{3}\left(\frac{CRPMX}{CRPHC+F}\right)_{t-1},\ CRPSP\cdot DE.P,\ Sd,\ X_9$$

where $CRPHT/DT\cdot MIN = \left[\left(\frac{CRPHT}{CRPDT}\right) - MIN\left(\frac{CRPHT}{CRPDT}\right) + 0.1\right]^{-1}$ and $\overline{CRPSP\cdot DE.P} = \left[\pi - \frac{d\varepsilon - \overline{d\varepsilon}}{\sigma_{d\varepsilon}}\right]^{-1}$,

$E(d\varepsilon - \overline{d\varepsilon}) = 0$, var $(d\varepsilon) = \sigma_{d\varepsilon}^2$, and π is determined by $Pr\left[-\pi < \frac{d\varepsilon - \overline{d\varepsilon}}{\sigma_{d\varepsilon}} < \pi/\phi = 60\right] = 0.9995$.

(10) Supply-utilization quarterly balance (identity) with linkage to annual crop productions

$$\Delta CRPHT = CRPSP\cdot\Omega_s \begin{cases} = \gamma_s \text{ for harvest quarters} \\ = 0, \text{ otherwise} \end{cases} + CRPMI - CRPDT$$

where the seasonal crop allocation factor is

$$\Omega_s \text{ and } \sum_{s=1}^{4}\gamma_s = 1\ (s = 1, \ldots, 4)$$

(11) Aggregate and individual demand components (identify)

$$CRPDT = CRPDF + CRPDH + CRPDS + CRPMX$$

II. Multistage crop production response (annual and recursive)

(12) Acreage, yield, and production identity

$$CRPSP = CRPSA\cdot\frac{CRPSH}{CRPSA}\cdot CRPSY$$

(13) Planting season acreage response

$$CRPSA\text{: } \frac{CRPPF}{CRPEU},\ \frac{CRPPF_j}{CRPPF_s},\ CRPPD,\ CRPPE,\ PASWC,\ X_{13}\ (j \neq s)$$

(14) Growing and harvest season analysis of yield per acre

$$CRPSY\text{: } CRPSA,\ \frac{CRPSH}{CRPSA},\ \frac{CRPPF}{CRPEU},\ T_{xy},\ X_{14}$$

III. Income and expenditure flow (quarterly and recursive)

(15) Determination of livestock cash receipts

$$CRLVK_i\text{: } LVKPF_i\cdot LVKAP_i,\ V_{15i}\ (i = 1, \ldots, 6)$$

(16) Determination of crop cash receipts

$$\ln CRC_j\text{: } \ln (CRPSP_j\cdot CRPPF_j),\ \ln CRPHF,\ S_d,\ V_{16j}\ (j = 1, \ldots, 11)$$

(17) Determination of total cash receipts

$$CR\text{: } \sum_{i=1}^{6} CRLVK_i + \sum_{j=1}^{11} CRC_j,\ Sd,\ V_{17}$$

(18) Realized gross farm income identity

$$YFRG = YFMGNP + CR$$

(19) Prices paid by farmers

$$\ln PFPC^*\text{: } \ln PDIBF,\ \ln LVKPFW,\ \ln FGPFW,\ \ln XAG,\ V_{19}$$

(20) Farm production expenses function

$$EXFP\text{: } XAG,\ PFPC^*,\ V_{20}$$

(21) Realized net farm income identity

$$YFRN = YFRG - EXFP$$

(22) Realized total farm income, identity

$$YFTN = YFRN + INFNC$$

Table 1. (continued)

Endogenous Variables

CR	= Cash receipts, total $ billion annual rate
CRLVK	= Cash receipts, livestock
CRC	= Cash receipts, crop
CRPDF	= Crop, domestic utilizations for feed
CRPDH	= Crop, domestic utilizations for food and industry
CRPDS	= Crop, domestic utilization for seed
CRPDT	= Crop, total utilized (disappearance)
ΔCRPHT	= Crop, changes in total stock
CRPMX	= Crop, total U.S. exports
CRPPF	= Crop, U.S. average prices received by farmers
CRPSA	= Crop, U.S. annual total acreage planted, crop year
CRPSP	= Crop, U.S. annual total production, crop year
CRPSY	= Crop, U.S. yield per acre harvested, crop year
EXFP	= Farm production expenses, $ billion annual rate
FGPFW	= Weighted average prices, feed grain
INFNC	= Net change in farm inventories, $ billion annual rate
LVKAP	= Livestock, commercial productions, live weight
LVKPF	= Livestock, average prices received by farmers
LVKPFW	= Weighted average prices, livestock
LVKRD	= Livestock, per capita retail demand, dress weight
LVKSF	= Livestock, animals on feed or hatchery operation, head
*PFPC**	= Average prices paid by farmers, index (1967 = 100)
YFRG	= Realized gross farm income, $ billion annual rate
YFRN	= Realized net farm income, $ billion annual rate
YFTN	= Total net farm income, $ billion annual rate

The key exogenous variables involve five major categories to reflect the simulation capabilities of the model: government policy, weather impact, general economic conditions, world economics and agricultural conditions, and the others.

Exogenous Variables

.WRHBP	= Average hourly earnings, U.S. bakery products industry
**MIN*	= Minimum value in the sample period
CRPEU	= Crop, index of fertilizer prices
CRPHC+F	= Crop, farm and commercial stock, beginning of quarter
CRPHG	= Crop, CCC stocks own facilities, beginning of quarter
CRPMI	= Crop, total imports
CRPPD	= Crop, U.S. effective diversion payment rate
CRPPE	= Crop, effective support rate
CRPSH/CRPSA	= Crop weather condition proxy, harvested acreage as percentage of planted acreage
CRPSP/DE	= Productivity trend, seed production
CRPSP·DE.P	= Crop nonlinear probability variable of crop forecast revision
DEV	= Exchange rate, SDR's per U.S. dollar
GDPW	= World domestic product, weighted by agricultural production (1968 = 100)
ΔLVKHT	= Livestock, changes in stock of cold storage
LVKMI	= Livestock, total imports
LVKMX	= Livestock, total exports
PASWC	= Range conditions, previous fall
PDCENF	= Implicit deflator, personal consumption expenditure of nondurables, food and beverage (1958 = 100)
PDIBF	= Implicit deflator, fixed investment, total (1958 = 100)
POP	= Population, world total
PROW	= Crop, world total production
RCLVK	= Livestock, farm-to-retail spreads
RDPI	= Real disposable personal income
Sd	= Seasonal dummy variable, 1 for the quarter and 0 otherwise
SOMPM44DE	= Soybean cake and meal prices
SPRMLK	= Milk, support price for manufacturing grade milk
STK	= Crop, carryover stocks, total for world major exporting countries
TCPOP	= U.S. total civilian population
TECGPL480$	= Volume of U.S. agricultural exports under PL-480
Tsy	= Crop, productivity trend of yield per acre
Vi	= Farm income, other exogenous variables and disturbance term

Table 1. (continued)

W_l	= Livestock, conversions factor from live weight to dress weight
XAG	= Gross product originating agriculture, forestry and fisheries
Xi	= Crop, other exogenous variables and disturbance term
YFMGNP	= Farm income—nonmoney and government payment
Zi	= Livestock, other exogenous variables and disturbance term
δ_l	= Weight factors, grain consuming animal units
β_L	= Distributed lag coefficients, second-order polynomial, with N period lags
$d\varepsilon$	= Crop, deviation from expectation of annual crop production
α_L	= Distributed lag coefficients, second-order polynomial with K period lags
ϕ	= Degree of freedom
Ω_s and γ_s	= Seasonal crop allocation factors

The proposed weather impact analysis is based on an evaluation of the crop expectation and realization process and its impact on price determination. The variable *CRPSP·DE.P* (equation (9)) is constructed for that purpose. Given early season crop production estimates (March planting intentions) as the baseline forecast, the subsequent revisions are defined as $d\epsilon$, where $d\epsilon$ is baseline forecast minus the subsequent forecast in a given quarter. Under normal weather conditions, $d\epsilon - \overline{d\epsilon} = 0$, so that *CRPSP·DE.P* is a constant $(1/\pi)$. Whenever extreme weather conditions develop, they can be measured in terms of standard deviations. Since *CRPSP·DE.P* is a nonlinear term, as the crop forecast is revised downward, the price impact increases rapidly. Therefore, this approach is useful for drought impact analysis.

The price determination formulation follows Adams and Behrman, who have treated stock-demand ratios in a nonlinear fashion as a principal explanatory variable in price equations. As the stock-demand ratio approaches the minimum historical level, the price impact increases rapidly. The same type of function is used in the export demand function (equation (8)) for which world stock and production variables are used.

A unique feature of the acreage and production response equations is the possibility of evaluating the crops through various seasons of a crop year. The impact of weather and government farm program can be fully analyzed with respect to planting, growing, and harvest ramifications. To link the annual crop production with the quarterly supply-demand-stock balance, a seasonal crop production allocations factor is used in equation (10).

Simulation Results

The theoretical relationships specified in the preceding section represent a simultaneous equation system of 249 equations, of which 101 are stochastic, the others being identities and definitions. This model was estimated by the ordinary least squares (OLS) method using data during 1945-74 for annual equations and from 1959.1 to 1974.4 for quarterly equations. Apparently, the direct applications on OLS to structural equation yield acceptable results regardless of built-in biases. Given the small sample available and the nonlinearities involved in the specification, the advantage of simultaneous equation estimators remains uncertain. Nevertheless, it may be useful to test the feasibility of an iterative instrumental variable procedure (Klein 1971a) for possible improvement in predictive efficiency.

In view of space limitations the estimated equations are not presented, nor do I attempt a detailed explanation of the results. In general the model shows quite satisfactory results in terms of the signs and magnitudes of the coefficients, goodness of fit, and other test statistics. Having examined the model equation by equation, the next logical step is to test it as a complete entity. Two basic simulation experiments have been carried out to test the model for its *ex post* forecasting performance as well as its sensitivity to exogenous shocks. Among the various criteria proposed for model evaluation (e.g., Dhrymes et al.), these two tests are most commonly employed prior to the release of the models.

The summary statistics of the *ex post* predictive testing in table 2 were taken from static and dynamic simulations of the complete model from 1968.2 to 1974.3. For comparison purpose I also include the single equation solution for the entire sample period. To perform this simulation experiment, the actual values of the exogenous variables and the initial values of the endogenous variables were used to solve the model simultaneously through an iterative procedure

Table 2. Error Analysis in the Wharton Agricultural Model

	Root-Mean-Square Error as Percentage of Mean		
		Complete Model Simulation	
	Single Equation (Sample Period)	Static (1968.2–1974.3)	Dynamic (1968.2–1974.3)
Prices, income, and expenditure			
Prices received by farmers	0.19	5.28	6.75
Prices paid by farmers	0.06	4.71	4.53
Total farm cash receipts	0.71	8.21	8.93
Farm production expenses	0.37	4.69	8.40
Realized gross farm income	Identity	9.00	10.04
Livestock (sample commodity: beef cattle)			
Cattle on feed 23 states (1,000 head)	0.76	3.53	7.97
Beef cattle, commercial liveweight slaughter (billion lbs.)	0.53	2.57	5.23
Beef per capita retail demand (lb./capita)	Identity	2.34	4.79
Cattle, average price received by farmers ($/cwt.)	0.81	4.43	5.11
Crops (sample commodity: corn)			
Corn, average price received by farmers ($/bu.)	2.14	14.60	15.53
Corn, utilized for feed (million bu.)	1.46	11.56	14.04
Corn, utilized for food and industry (million bu.)	0.37	3.14	3.16
Corn, total change in stocks (million bu.)	Identity	7.47	8.98
Corn, total exports (million bu.)	2.67	16.94	16.88
Acreage planted, yield, and production (sample commodity: corn)			
Corn, acreage planted (million acres)	0.66	4.41	8.98
Corn, yield for grains (bu./acre)	1.08	6.53	6.52
Corn, production for grain (million bu.)	Identity	6.94	7.09

with a convergence factor of 0.5%. The predictive capabilities of the model are described by the root-mean-square error as a percentage of the sample mean. Cattle and corn were chosen to represent the livestock and crop sectors, respectively. The resulting statistics indicate that during one of the most difficult time periods for agricultural forecasts the model performs quite well. Most of the endogenous variables are tracked very closely by the model, particularly the overall farm price indexes, farm income, and farm expenditure components. At the commodity level, the livestock forecasts are generally better than crops. The price and export demand functions of corn are relatively poorer performers, but their prediction errors in the dynamic simulation are quite similar to those in the static solution. This phenomenon is particularly encouraging because error accumulation has long been recognized as a serious problem to dynamic predictions.

The second simulation experiment concerns the model's ability to respond to external shocks. First, a "control" solution is calculated and then one or more of the exogenous variables are changed by a preassigned amount to generate a "disturbed" solution. One of the most interesting simulations is the drought impact analysis on crop prices. We would expect that the extreme weather conditions of 1973–74, the so-called triple whammy of spring flood, summer drought, and early frost, had strong upward price effects in the year. The drought impact analysis was calculated by assuming "normal weather" conditions, which implies that the early season crop production expectation (March planting intention multiplied by normal yield) remain unchanged until actual harvest. From this simulation experiment, the "normal weather" corn prices were found to be $2.29 and $2.40 per bushel in 1974.3 and 1974.4, compared with the actual prices of $3.19 and $3.34 in the same period. To summarize the simulation experiments, the model shows promise for short-term forecasting and analysis. While development of im-

provements and enhancements will be a continuing effort, we hope to learn a great deal from repeated applications to *ex ante* forecasting.

Agricultural Activity and the General Economy: Some Macromodel Experiments

Joseph M. Roop and Randolph H. Zeitner

Spectacular growth in the size and complexity of econometric models has undoubtedly aided economists in understanding relationships within the macroeconomy. These models are not wholly satisfactory in the view of agricultural economists because they have no agricultural sector that allows an investigation of the interaction between the macroeconomy and agriculture. This is unfortunately true, despite the fact that a number of agricultural sector models have been developed specifically for inclusion within a large macromodel (e.g., Cromarty, Fox).

Macromodel builders have adopted one of two strategies to capture the effects of agriculture on the macroeconomy. They either structure agriculture as a satellite model or consider the important behavioral variables in the agricultural sector as being determined outside of the macroeconomic model. A satellite model is separate from the macromodel in the sense of providing no estimates of endogenous variables but relies on forecasts of variables generated by the macromodel (Adams). The second strategy considers agriculture as an industrial sector but relies on variables outside the model to better characterize the impacts that agriculture has on the macroeconomy; i.e., the sector is treated as essentially exogenous.

The aim of this study is first the construction of an agricultural sector model that is self-contained and could be run as a small satellite model and, second, the integration of the agricultural sector model into a large macromodel, in this instance the one developed by Wharton Econometric Forecasting Associates known as the Wharton Mark IV.

Joseph M. Roop and Randolph N. Zeitner are economists with the National Economic Analysis Division, Economic Research Service, U.S. Department of Agriculture.

The authors wish to thank Steven Guebert and Terry N. Barr for helpful suggestions on earlier drafts of this paper.

The interested reader can find a discussion of the predecessors of the Mark IV in Evans and Klein and in McCarthy. For the purpose at hand, the agricultural sector of Mark IV is discussed in the following section. The agricultural sector model is then described, tested as a satellite, and then integrated into Mark IV by eliminating some of the Wharton specified equations and adding our own. The concluding section summarizes our work up to this point and suggests some of the ways we plan to further this work in the future.

Wharton Mark IV Agricultural Sector

Five behavioral equations in Mark IV describe economic activity within the agricultural sector. Fixed nonresidential agricultural investment (*IAAG*) is determined by the ratio of the implicit price deflator for agricultural output to the user cost of capital, a distributed lag of past output, and lagged value of the estimated error (Cochrane-Orcutt technique). Output originating in agriculture (*XAG*) is determined by only one explanatory variable, personal consumption expenditure for nondurable food and beverages. The implicit deflator associated with *XAG* (*PXAG*) is determined by prices received and prices paid, both taken as exogenous. Compensation per man-year (*WRCAG$*) is determined by distributed lags of three explanatory variables, the potential unemployment rate (*CVWNRUT*), the consumer price index (*PC**), and the ratio of output to agricultural employment (*XAG/NEHA*). The ratio of proprietary farm income (*YENTF$*) to the current value of agricultural output is explained by the ratio of prices received to prices paid (*PFR** and *PFPC**, both exogenous variables).

The linkages of the implied agricultural sector with the rest of the economy are both direct and indirect. Farm investment and the change in farm inventories (*IBIF*, considered exogenous) in real terms are elements of aggregate investment demand, a component of real gross national product (GNP). Output originating in agriculture is added to other industry outputs and reconciled with the GNP. After prices are computed, including the implicit deflator for agricultural output, the current value of GNP is determined. National income, including proprietary farm income, is calculated by an identity relation that includes the wage bill in agriculture. Farm prices received enter directly into the determination of the unit value index of food exports (*PTEEGDF*) and the change in the wholesale price index of crude materials (*PWPC**). In an indirect fashion, the implicit sector deflator (*PXAG*) enters into the determination of most other implicit deflators. All the implicit deflators for the components of aggregate demand are estimated as a ratio to weighted averages of the industrial sector implicit deflators, the weights having been derived from a separate input-output study. Thus, a current quarter increase in *PXAG* will enter into the determination of most other prices in the same quarter.

An Aggregate Agricultural Sector Model

The main distinction between the proposed agricultural sector model (AGSEC) and the sector model described in the previous section is that AGSEC relies on the income statement as used in the National Income and Product Accounts (U.S. Dep. Commerce). By this definition, current output includes the value of commercially sold goods, the value of home consumption, rents, and the change in farm inventories. From total output, intermediate purchases are subtracted and other items added to yield gross farm product. Farm income is derived by adding transfer payments and subtracting both capital consumption allowance and indirect business taxes. Income can then be disaggregated into four components: wage compensation, interest, proprietors' income, and profits. This sector income statement is contained in the following three identities (table 1 contains a description of the variables):

Table 1. Variable Identification

Variable	Description
CCARNTAG	Depreciation rate, agriculture
CENF	Consumption expenditure, food
CRCCC	Cash receipts plus net CCC loans
CUWIPMFD	Capacity utilization index, manufacturing durables
CVWNRUT	Potential unemployment rate, civilian labor force
CCAAG	Depreciation expenses, agriculture
DPVAG	Discounted current value of depreciation
DUMDOCK	Dummy for dock strike
DUMITL	Dummy, investment tax credit, Long amendment
DUMSA01(02,03)	Seasonal dummies, first to third quarters
DUMTIME	Dummy, time
FMRCS	Yield on corporate bonds
IAAG	Investment, new plant and equipment, farm
IBIF	Change in farm inventories, constant dollars
IBIF$	Change in farm inventories, current dollars
ITREAG	Effective investment tax credit rate
KIAAG	Capital stock, agriculture
KIBIF	Real value of inventories
LQTAG	Effective tax life, agricultural equipment and structures
NEHA	Agricultural employment
OER	Other exogenous receipt items
OI	Other items
OPEXP	Purchases of intermediate products
*PC**	Consumer price index, all items
PDCENF	Implicit deflator, *CENF*
PDIBFN	Implicit deflator, total fixed investment
*PFPC**	Prices paid, farm
*PFR**	Prices received, farm
*PFR*12*	Thirteen-period moving average of *PFR**
PTEEGDF	Unit value index, exports, food
*PWPC**	Wholesale price index, crude materials
*PWPI**	Wholesale price index, intermediate materials
*PWPFP**	Wholesale price index, finished producers goods
PXAG	Implicit deflator, agriculture
RIRAG	Intermediate variable used in computation of *UCKAG*
TAG-IBT	Transfer payments less indirect business taxes
TXRITEFAG	Effective corporate tax credit rate, agriculture
UCKAG	User cost of capital, agriculture
WBCAG$	Wage bill in agriculture
WRCAG$	Compensation per man-year in agriculture
WRCMF$	Compensation per man-hour in manufacturing
XAG	Output originating in agriculture, real terms
XAG$	Current value of *XAG*
XQMKT	Index of volume of marketings

Table 1. (Continued)

Variable	Description
YCORP	Net corporate income in agriculture
YENTF$	Net farm income, proprietors
YOAGI	Interest component of income in agriculture
YPDPC$	Disposable personal income per capita
YAG$	Income originating in agriculture

(1) Gross farm product (*YAG$*):

$$\underset{(w)}{XAG\$} = CRCCC + \underset{(w)}{IBIF\$} + OER - OPEXP + OI,$$

(2) Farm sector income (*YAG$*):

$$YAG\$ = XAG\$ - CCAAG + (TAG - IBT),$$

and

(3) Net proprietors' farm income (*YENTF$*):

$$\underset{(w)}{YENTF\$} = YAG\$ - \underset{(w)}{WBCAG\$} - YOAGI - YCORP.$$

The parenthetical *w* denotes variables in the agricultural sector of Mark IV.

The major structural components of *AGSEC* are described by equations that estimate farm prices received (*PFR**), prices paid (*PFPC**), an index of the quantity of marketings (*XQMKT*), and the value of intermediate products (*OPEXP*). Both price equations are estimated as price-dependent derived-demand equations for outputs and inputs of the farm sector. The value of intermediate products is estimated recursively based on the value of current output and prices paid for inputs. The quantity of marketings is estimated as a business response variable allowing *XQMKT* to respond to current price, an expected normal price, and the current value of inventory stocks. The variable *XQMKT* is a Paasche index constructed to allow the determination of the major component of total output—cash receipts—by the following identity:

(4) Cash receipts (*CRCCC*):

$$CRCCC = PFR^{*} \cdot XQMKT \cdot 0.042825.$$

A flow diagram in figure 1 provides an overview of the structure of the model. For those interested in more detail, the estimated equations are available upon request.

The restructured model of the agricultural sector (AGSEC) contains nine behavioral equations, the four previously cited plus one for each of the following: investment (*IAAG*), employment (*NEHA*), implicit sector deflator (*PXAG*), wage compensation per man-year (*WRCAG$*), and depreciation expense (*CCAAG*). In addition to the four identities mentioned, there are identities for current value of inventory changes and stocks, the current value of investment, user cost of capital, the wage bill, and the real value of farm output.

All behavioral relations were estimated by ordinary least squares over 1955–75. Adjustments were made for autocorrelation using the Cochrane-Orcutt iterative technique. There are a total of twenty variables exogenous to AGSEC, nine of which are endogenous to Mark IV. The version of Mark IV reported in this paper contains 460 endogenous variables and 207 exogenous variables. Thus, when AGSEC and Mark IV are solved together, there are 469 endogenous variables and 216 exogenous variables.

AGSEC as a Satellite: Solution and Simulations

AGSEC cannot be solved by deriving the reduced form from a linear transformation of the structural parameters because the model is nonlinear. To solve the model, the Gauss-Seidel iterative solution technique, as documented in Heien, Matthews, and Womack, is used. Both static and dynamic simulations were performed over 1969–75, years which were included in the period of fit. Summary measures for both simulations are given in table 2.

The variables directly estimated have smaller percentage errors than those solved through identities. Seven of the variables have a mean percentage error greater than 5%, four of which are derived from accounting identities. One would expect that the system would perform better when actual lags are used (static simulation) rather than when lags are computed (dynamic). Table 2 affirms this supposition in this case if the criteria are anything but the Theil *U*-statistic. In the static simulations, twelve variables

perform "worse" than a naïve no-change model, while in the dynamic simulation only four are worse. For either simulations, these Theil U-statistics are disturbing. We conjecture that the model's performance can be substantially improved (in the concluding section this is elaborated on). Table 2 also reports static and dynamic simulation performed over the period 1975I–76II, the latter two quarters outside the sample period used for estimation.

For an understanding of the response dynamics of AGSEC, various multiplier analyses were performed, i.e., both impact (or one period) and longer (up to twenty periods). Since the total system is nonlinear, the effect of an increase in an exogeneous variable may not, in general, be the same as a decrease; but we expect them to be quite similar. Several of the multipliers are shown in table 3.

Unfortunately, a variable of considerable interest to the U.S. Department of Agriculture, net farm income (*YENTF$*), still has a large percentage error. Primarily for this reason, we feel that exploiting the model for policy implications at this time would be premature. As work progresses and we are better able to validate the structure of the model, we will be better able to replicate historical experience. Despite these obvious shortcomings, we decided to embed the model for two major reasons: to "debug" the software, and to see how the macroeconomic model would be affected by an altered agricultural sector.

Integrating AGSEC and Mark IV

The solution software provided by Wharton Econometric Associates for solving the Mark IV model consists of a generalized Gauss-Seidel solution routine (the SOLVE program) using two subroutines (CONNIE and SIMON) to solve a model coded in FORTRAN. The CONNIE subroutine solves for the constant part of each equation, including any lagged predetermined variables, while the SIMON subroutine is used to solve for the current period simultaneous values. To embed the agricultural sector model into the Mark IV, the FORTRAN coding of the Mark IV was modified to eliminate the computation of variables specified by the model and augmented with additional subroutines containing the equations of AGSEC. A one-period, static simulation was then performed from 1974I–76I with both the augmented model again called AGSEC and the unaltered Mark IV (Mark 4).

A number of technical points are worth mentioning before reporting results. Time did not permit the variety of experiments we would like to have conducted nor has validation of AGSEC proceeded to the point where we feel confident that the important interactions between the agricultural sector and the macroeconomy are being captured; consequently, the results must be taken as illustrative rather than as an expression of the effect of the agricultural sector on the macroeconomy. The results show the impact on the macroeconomic model of the "raw" agricultural sector model, not one altered by constant adjustments to better replicate historical experience. Even though constant adjustments have not been used, the results are encouraging. Finally, space limits do not permit the reporting of many agricultural sector variables, so instead reporting of results is limited to macroeconomic variables on which one would expect an impact as a result of tinkering with the agricultural sector.

Six variables that might be affected by

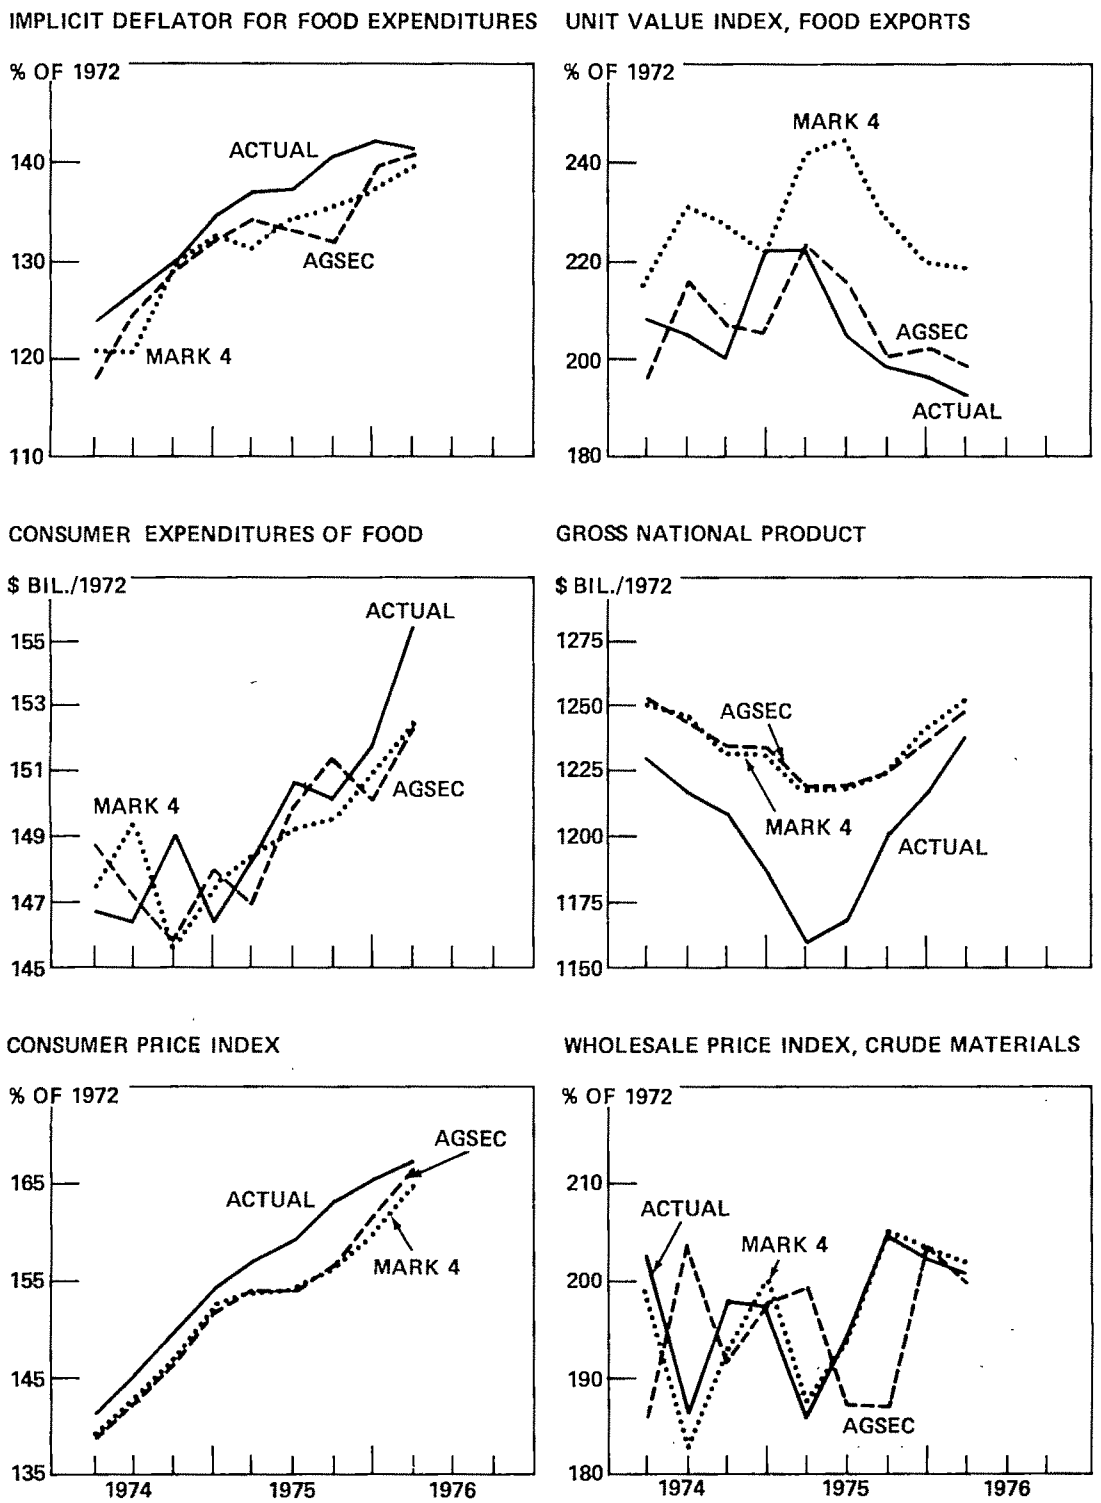

Figure 2. Plots of simulated values for Mark IV, AGSEC, and actual values of selected macroeconomic variables

restructuring the agricultural sector of Mark IV are shown in figure 2. Even a cursory glance at figure 2 suggests that any respecification of the agricultural sector of a large macromodel will considerably alter the results. Even for the consumer price index the

agricultural portion of which is quite small, the alteration of the agricultural sector makes a noticeable difference, though not a large one. In two cases, in the estimation of *CENF* and *PWPC**, AGSEC seems to introduce a systematic one-quarter lag in the direction of change. For the wholesale price index, which is driven by the exogenous variable *PFR** in Mark IV, this systematic lag is understandable since *PFR** is endogenous in AGSEC and exhibits the same one-quarter lag. But for *CENF*, the systematic lag is unexpected. In one case, *PTEEDGF*, the AGSEC augmented model clearly improves its performance considering either levels or direction of change. In the other cases shown in figure 2, the differences suggest that there is little difference in results.

These results suggest that altering a large macroeconomic model by changing the structure of its agricultural sector will have a significant effect on the values predicted by the model. The results at this juncture, however, do not warrant the conclusion that prediction will be improved.

Summary and Conclusions

This paper has demonstrated that an aggregate agricultural sector model can be structured on the basis of the income accounting identities of the farm sector and then embedded into a large macroeconomic model. Simulations and a prediction interval test of the model as a satellite outside the period of fit suggest that specification of the model can be improved. Results of simulating the large macroeconomic model with the embedded agricultural model suggest that some measures of predictive performance are improved, others show little or no change, while others predict with less accuracy.

Throughout this paper we have attempted to refrain from unwarranted statements and conclusions. The ultimate goal of this research is the development of an agricultural sector model based primarily on aggregate data and embedded within a larger macroeconomic model. The purposes of such a model are manifold: it could be used to examine the impact of proposed policies, both agricultural and otherwise, and for short-term forecasting of agricultural aggregates to augment the USDA's current situation and outlook efforts; and it could contribute to knowledge of how agriculture and the rest of the economy affect each other.

The caution arises from a disinclination to have the current model used for any of these purposes. This paper is no more than a status report on this development work. Current plans call for considerable refinement of the model, including disaggregating the farm price and marketing equations to generate cash receipts for, at least, livestock and feed. In addition to this horizontal disaggregation, we plan some vertical disaggregation to better describe the effects of farm market phenomena on wholesale and retail food prices and the effects of agricultural and other exports and imports on the agricultural sector.

We also plan to alter our strategy with respect to the use of the national income accounting identities. We currently accept the change in farm inventories as exogenous. This allows derivation of the real value of agricultural output through identities, thus implying a supply response in real terms that takes little account of the other real variables in the system. We plan to alter this by estimating real output directly allowing inventory changes to adjust in order that the identities be satisfied.

At this point conclusions can only be tentative. They are nonetheless suggestive of at least two things: a macroeconomic model may be substantially altered by a change in what is one of the relatively smaller sectors of the total economy, and the project is feasible, and in our opinion, a promising one.

Price Determination Processes for Agricultural Sector Models

Dale Heien

Until recently, traditional subsector model analysis for agricultural products had focused largely on supply-acreage considerations. This was particularly true of the crops sector, where historically supply has outstripped demand, leaving market prices at support levels. Supply response equations often used the support price as the supply price, reducing even further the role of market prices. However, the disappearance of excess capacity from agriculture has shifted attention to the demand-price side of the ledger. Recent experience with worldwide grain price inflation and its impact on domestic livestock prices has reinforced the need to consider further the price determination mechanism for agricultural products. Traditional concern with supply response in an environment of excess capacity centered around the farm income problem, i.e., the relative decline of rural America. Analysis of this problem has been the prime concern of agricultural policy makers since the 1930s. On the other hand, high food prices have been the source of recent political concern, not only because of their direct effect on the cost of living but also because of "second-round" inflationary effects due to increased wage demands. These higher wages in turn lead to inflationary pressures of their own in the nonfood sectors of the economy. Hence, price determination is an appropriate topic for a session on econometric models since, as will be shown, the nonfarm economy plays a large role in that process.

Economists, both agricultural and otherwise, have historically paid relatively little attention to the price determination process. For the nonfarm sector, the first serious effort at price modeling came from the Eckstein-Fromm price equation. A simplified version of macro model price behavior is as follows. Demand determines output; the difference between actual and potential output (i.e., unemployment) and lagged prices determine wages; wages and output determine prices. Various refinements of this basic approach are the mainstay of most aggregate models, although some have been revamped with a stage-of-processing model along the lines developed by Popkin.

The price determination process for agricultural models can be summarized as follows. Lagged prices, costs, government programs, weather, and the carryover determine supply; output and price expectations determine stock levels; the difference between stocks and supply is identically equal to demand; demand is determined by prices and income. This yields a system of four equations in four unknowns. Hence, price is determined by the interaction (i.e., the intersection) of supply and demand. This conceptualization places a large burden on the stocks equation in the price determination process. The consequences of this specification, while not readily apparent when examining single equation results one at a time, become evident in complete solutions. Since errors of substantial magnitude are not uncommon in stocks equations, the prices generated in this manner are also subject to considerable error. One obvious answer to this problem is to improve the stocks equation. This is difficult for several reasons. First, ending stocks are typically the entry that balances the supply and utilization tables. Hence, they become the depository for measurement error throughout the system. Second, only a portion of stocks is due to intended, rational behavior on the part of businessmen. Some portion of stocks are unintended accumulation (or depletion), i.e., the difference between supply and demand when the businessmen's desired stocks are added to demand. Third, knowledge of the range of motives for holding stocks and how to model these motives is at best meager.

Dale Heien is a private economic consultant in Washington, D.C.

The author is indebted to the staff of the Economics Branch, Agriculture Canada, for helpful comments on this paper, especially Sean Chin, Zuhair Hassan, and Gordon MacAulay.

The notion of enumerating variables and equations, strongly reinforced by a tradition of linear specifications and matrix solutions, led to a further obscuring of the price determination process. Solution techniques such as the Gauss-Seidel method require normalization. (For a technical discussion of this technique, see Heien, Matthews, and Womack.) For each endogenous variable in the model, there must be a unique structural equation with that variable as the dependent (left-hand-side) variable. The strict interpretation of this requirement is that each variable in any given econometric system has a unique causal structure.[1] This is, of course, a mathematical requirement and as such has no particular economic significance. However, Fisher has given economic interpretation to this requirement by posing the following problem. Assume that all variables in a given model are caused by other variables (in the same system) acting with some time lag, no matter how small, i.e., a causal chain system. This is an extremely plausible assumption. When these relations are aggregated over time (e.g., from days to months or months to years) the resulting system is no longer a causal chain type but is now fully simultaneous. More importantly, it is also a simultaneous model with a unique dependent variable for each equation in the model. Hence, what was a completely recursive system becomes, when aggregated over time, a simultaneous system normalized in the Gauss-Seidel manner.

The importance of this result is that if the notion of lags between cause and effect is accepted, the resulting simultaneous model is normalized in a causative sense. Mere counting of equations and unknowns no longer suffices.[2] This requires a causative specification for each variable in the system including, of course, prices. Acceptance of this notion implies that the traditional supply, demand and stocks specification, is erroneous. One of the equations must be normalized on price. One solution to this problem has been the introduction of the idea of price dependency to the demand relation.

[1] This in no way contradicts the notion of a system of simultaneous (i.e., jointly dependent) equations.

[2] Mere counting of the equations and unknowns, of course, did suffice. It is assumed here that the rank and order conditions are fulfilled.

The Notion of Price Dependency

The idea of price dependent relations goes back to the early foundations of agricultural economics. Sewell Wright in 1921 perceived the causative nature of prices in this sense (Fox). The basic idea underlying this notion is that for most agricultural products total output is predetermined in the short run, due to the role of past prices in the supply relation and the time required for new acreage to be brought into production or for livestock herds to be expanded. With supply virtually predetermined, the only possible variation remaining in the system is either in stocks or price. In the short run, stocks can vary a great deal relative to demand. However, over the period of a year, storage facilities are limited. Hence, stock level variation is also somewhat limited, which is particularly evident when annual stock-consumption ratios are compared with monthly or quarterly ones. Over the course of a year, stock levels, particularly for meats, are relatively stable, implying that prices are determined by the demand for the product in question. At this point the question is which demand—farm or retail? One can use farm level and then arrive at the retail price through the use of a margin equation that relates the retail price to the farm price and other processing costs. This specification is appropriate but in a different context that will be discussed later. Waugh took the position that over long time periods (which is the case here) retail demand was the determining factor and the farm-level demand was a derived demand.

When considering models in an annual framework, the position taken by Waugh is a more fruitful approach and is consistent with the recent theoretical work by Gardner. From a conceptual point of view, the model outlined here is similar to that used by Gardner. However, in order to empirically implement such a model, normalization decisions must be made for each relation. The type of model envisioned here may be specified as follows. The retail food product (P) is a function of the farm product input (F) and, for simplicity, a "bundle" of processing and marketing services (B), or

$$P = g(F, B). \tag{1}$$

Letting the price of a good in question be represented by its lower case letter, the supply relation for the farm product is F

$= g(f_{-1})$. The retail demand may be specified in several ways, which are discussed below. For the present, the retail demand is written as the price dependent relation $p = g\{P^d, z\}$, where P^d is quantity demanded and z is other factors such as income. Converting equation (1) to a supply relation under competitive conditions gives

$$(2) \qquad P^s = g\{(p/f),(p/b)\} \quad \text{and} \quad P^d - P^s = S,$$

where S is stocks, and $S = g\{P^d\}$ so that $P^d = f\{P^s\}$. Under competitive conditions

$$(3) \qquad f/p = g'(F, B).$$

Using equations (2) and (3), the demand for the farm level input can be expressed as

$$(4) \qquad F = g\{(p/f),(p/b)\}.$$

However, noting that F is already determined, equation (4) is inverted to give the price dependent factor demand curve

$$(5) \qquad (f/p) = g\{F,(p/b)\}.$$

If, for example, the production process is given by a Cobb-Douglas production function $P = aF^{\alpha}B^{\beta}$, then the analog for equation (5) is

$$(6) \qquad (f/p) = aF^{-\gamma}(p/b)^{\theta},$$

where $\gamma = (1 - \nu)/(1 - \nu + \alpha)$, $\theta = \beta/(1 - \nu + \alpha)$, and $\nu = \alpha + \beta < 1$. Hence, $\gamma > 0$, $\theta > 0$, and $\partial f/\partial p \cdot p/f = 1 + \theta$. When food prices fall (or rise), they fall (rise) further at the farm level than at the retail level. The above is a possible explanation of this observation. Equation (6) is also the "farm-retail margin." Increases in marketing costs in equation (6) will lower the farmers' share, while decreases in farm level output will increase it. A complete analysis of the margin is only possible through analyzing the complete set of relations, such as was done by Gardner.

Examples of the empirical implementation of these relations are given below for fed heifers and steers and barrows and gilts:[3]

$$(PFEC/RPB) = 23.57 - \underset{\substack{(4.1)\\ 0.12}}{0.20}FBHSS + \underset{\substack{(2.6)\\ 0.23}}{5.72}(RPV/CVBP),$$

$$\bar{R}^2 = 0.77 \quad \text{and} \quad D.W. = 1.46;$$

$$(FPP/RPP) = 8.89 - \underset{\substack{(0.4)\\ 0.09}}{0.052}TNPS - \underset{\substack{(0.8)\\ 0.20}}{9.65}(TNPS/CAP) + \underset{\substack{(5.9)\\ 0.83}}{27.3}(RPP/WRMP) + \underset{\substack{(1.6)\\ 0.38}}{0.162}T,$$

$$\bar{R}^2 = 0.85 \quad \text{and} \quad D.W. = 2.04;$$

where *PFEC* is price of fed cattle, *RPB* is retail price of beef, *FBHSS* is fed beef heifer and steer slaughter, *CVBP* is cost variable for beef processors, *FPP* is farm price of pork, *RPP* is retail price of pork, *TNPS* is total number of pigs slaughtered, *CAP* is capacity in the pork industry, *WRMP* is wage rate meat processing industry, and *T* is a time trend. These relations were fit over the 1950–70 period by ordinary least squares.

The notion of price dependency can also be fruitfully applied at the retail level. The specification of retail demand begins with the theory of the budget of the consumer. The consumer is assumed to maximize a static single period utility function

$$(7) \qquad U = f(q_1, \ldots, q_n)$$

subject to the budget constraint

$$m = \sum_{i=1}^{n} p_i q_i.$$

This maximization process yields the demand relations,

$$(8) \quad q_i = f_i(p_1, \ldots, p_n, m) \text{ for } i = 1, \ldots, n.$$

In view of the homogeneity restriction, these relations may also be written as

$$(9) \quad q_i = f_i(z_1, \ldots, z_n) \qquad \text{for } i = 1, \ldots, n,$$

where $z_i = p_i/m$ and are called normalized prices. Due to the large number of prices and quantities required, the above system is not empirically manageable. (An exception is an

[3] The figures below the coefficients are the *t*-ratios. The figures below the *t*-ratios are the elasticities.

approach such as Frisch's. For empirical implementation of this approach, see Brandow, George and King, and Hassan and Johnson.) Empirical demand analysis, following the theoretical system of Marshall, turned to real-income relative-price system of the form

$$(10) \qquad q_i = \alpha + \beta(p_i/p) + \gamma(y/p),$$

where p is the price of all goods. This system, with various modifications, has formed the basis for the majority of applied demand analysis. Cast in a price dependent form, the above relation is estimated as $(p_i/p) = \alpha/\beta + (1/\beta)q_i - \gamma/\beta(y/p)$, Hence, if $\gamma > 0$ and $\beta < 0$, income increases have a positive effect on the own price. In order to consider the case of substitute goods, equation (10) is written in double-log form:

$$(11) \qquad q_i = \alpha(p_i/p)^{\beta}(p_s/p)^{\theta}(y/p)^{\gamma},$$

where p_s is the price of a close substitute. In order for s to be a substitute, $\theta > -\gamma w_j$. Since the budget share w_j will be quite small ($\simeq 0.03$ for beef), θ may be taken as a positive number. Rearranging equation (11) as a price dependent relation gives

$$(12) \qquad (p_i/p) = \alpha q_i^{1/\beta}(p_s/p)^{-\theta/\beta}(y/p)^{-\gamma/\beta}.$$

From equation (12), for $\gamma > 0$, $(\partial p_i/\partial y)(y/p_i) = -\gamma/\beta > 0$, $(\partial p_i/\partial p_s)(p_s/p_i) = -\theta/\beta > 0$, and $(\partial p_i/\partial p)(p/p_i) = 1 + (\gamma + \theta)/\beta \lesseqgtr 0$. Since it is likely that $|\gamma + \theta| > |\beta|$, it is also likely that $(\partial p_i/\partial p)(p/p_i) < 0$, i.e., increases in the overall price level have a depressing effect on the price of the good in question. The economic explanation is that as the price level increases real income falls, shifting the demand curve downward and causing a fall in price. An increase in the price of a close substitute shifts the demand upward, causing price to rise. This is another way of looking at Hicks' proposition that the prices of close substitutes move together.

One can extend theory of the budget of the consumer in a manner to accommodate the notion of price dependent demand curves while retaining the theoretical rigor of utility analysis. This can be accomplished through the use of what Samuelson has called "mixed" demand systems. Substituting the demand equations given by equation (9) into equation (7) gives

$$(13) \qquad U = f(z_1, \ldots, z_n),$$

or the "indirect" utility function. Minimization of equation (13) subject to $1 = \sum_{i=1}^{n} q_i z_i$ gives the inverse demand equations:

$$(14) \quad z_i = f_i(q_1, \ldots, q_n) \qquad \text{for } i = 1, \ldots, n.$$

In the above system the prices are the variables and the quantities are given, i.e., the opposite of the conventional case. In the mixed system, some of the prices are assumed given. For the remainder of the goods, the quantities are predetermined, or

$$U = f(q_1, \ldots, q_h, \bar{q}_{h+1}, \ldots, \bar{q}_m, \bar{z}_1, \ldots, \bar{z}_h, z_{h+1}, \ldots, z_n).$$

Optimization of the above function yields the mixed demand system

$$q_i = f_i(z_1, \ldots, z_h, q_{h+1}, \ldots, q_n) \qquad \text{for } i = 1, \ldots, h$$

and

$$z_j = f_j(z_1, \ldots, z_h, q_{h+1}, \ldots, q_n) \qquad \text{for } j = h + 1, \ldots, n.$$

As discussed above, the supply and, with relatively fixed stocks, the demand for many agricultural products is given. Applying the mixed demand system to livestock products, for example, the demand for beef, pork, and poultry are assumed to be given as are the prices of all other goods. The resulting demand functions give the normalized price of beef as a function of the quantities of beef, pork, and poultry and the normalized price of all other goods. A set of these mixed demand relations were estimated for beef, pork, and broilers for the U.S. economy using annual data from 1950 to 1970. The results are given in table 1.

With supplies of beef, pork, and poultry relatively inelastic in the short run, the effect of changes in money income (*PCENDS*) and other prices (*PAO*) are the main short-run determinates of meat prices. Table 2 gives the reduced form elasticities for the retail price of pork (*RPP*), beef (*RPB*), and broilers (*RPC*) with respect to *PCENDS*, *PAO*, and real income (*PCENDS/PAO*).[4] Hence, in pe-

[4] The elasticities in table 2 were computed from a livestock

riods of rapidly increasing real income such as 1973, meat prices increase substantially. In the long run the price increases are ameliorated by the increased supply response, which eventually lowers prices. However, short-run spurts in real income give rise to food price increases that have political repercussions. Hence, stabilization of aggregate demand may help to stabilize food prices and avert costly and disruptive price controls.

Estimation of demand curves in the mixed system form also has several advantages from a statistical point of view. First, because they are close substitutes, prices of livestock products tend to move together, creating problems of multicollinearity when demand curves are estimated in the conventional manner. There is less collinearity between the quantities consumed of livestock products, due mainly to differing production cycles. Second, if in fact supply is relatively exogenous and relatively nonstochastic, then most variation occurs in price as it adjusts to clear the market. Hence, the assumption of fixed (nonstochastic) regressors is more closely fulfilled under the mixed specification.

The Notion of Excess Demand

The specification of price determination outlined above was essentially an empirical approach to a static equilibrium model. For annual frameworks, where adjustment lags in price formation can be ignored, the price-dependent notion is satisfactory. However, in quarterly and monthly models some account must be taken of inertia and disequilibrium even in competitive markets. At the heart of the disequilibrium model is the notion that supply and demand are not in balance, which is most widely articulated in the literature on the Phillips curve. The rate of excess demand in any market is defined as supply minus demand divided by supply, or $(S - D)/S$. For the labor market, the rate excess demand is the unemployment rate. The Phillips curve relates the rate of change of money wages to the unemployment rate. Hence, when supply and demand are in balance, wages do not change. Without going into the elaborations and refinements of the Phillips curve, the same approach can be applied to agricultural products. For agricultural commodities the difference between supply and demand is the change in stocks. Take, for example, the Phillips curve for corn,

$$(15) \qquad \dot{PC} = f\{(BSC - ESC)/SC\},$$

where *PC* is the price of corn, *BSC* and *ESC* are beginning and ending stocks, respectively, and *SC* is the supply. Since at the beginning of the crop year, *SC*, *BSC* and PC_{-1} are given, equation (15) becomes

Table 2. Short-Run Reduced Form Elasticities for Retail Prices of Pork, Beef, and Broilers

	PCENDS	*PAO*	*(PCENDS/PAO)*
RPP	2.20	−0.74	0.86
RPB	2.66	−1.66	0.36
RPC	1.74	−0.74	0.87

model that included endogenous (though highly inelastic) supply. For a description of this system, see Heien, Kite, and Matthews.

$$(16) \quad PC = f\{ESC, \overline{BSC}, \overline{SC}, \overline{PC}_{-1}\}.$$

Equation (16) emphasizes the role of stocks in determining grain price. Once planting intentions are known, the main determinant of each fall's supply is weather. As the crop year progresses, more and more information becomes available concerning the total crop. Better data on acreage planted becomes available, as does data on weather (e.g., rainfall at critical stages of crop growth). This information in turn affects the present price in the auction market. Demand information has a similar impact. Knowledge of an unexpected grain sale to Russia will reduce expected carry-over and hence raise grain prices. An example of this approach is

$$PC = \underset{}{0.535} + \underset{(5.6)\ 0.90}{0.945\,PC_{-1}} - \underset{(1.8)\ 0.20}{0.43\,EUSC}$$
$$- \underset{(2.3)\ 0.26}{0.115\,ECSC} + \underset{(1.8)\ 0.20}{0.02T},$$
$$\bar{R}^2 = 0.79 \quad \text{and} \quad D.W. = 1.36,$$

where $EUSC$ and $ECSC$ are ending government and commercial corn stocks, respectively.

The notion of excess demand can also be applied in other ways. For example, the demand for dairy products made from manufacturing grade milk is composed of the demand for butter, frozen products, evaporated and condensed milk, cheese, and dry milk. These can be converted to pounds of milk through known conversion factors and the excess demand approach used. On the other hand, an index of dairy product demand can be computed using some base year demand as weights. The ratio of this index to supply is then a measure of excess demand. An example of such an approach, taken from Heien, is

$$PMGM = \underset{}{-0.46} + \underset{(3.2)\ 0.48}{0.67(LIDPQ/QMGM)}$$
$$+ \underset{(4.1)\ 0.65}{0.66\,PMGM_{-1}},$$
$$\bar{R}^2 = 0.94 \quad \text{and} \quad D.W. = 1.63,$$

where $PMGM$ is price of manufacturing grade milk, $LIDPQ$ is Laspeyres index of dairy products demands, and QMGM is quantity of manufacturing grade milk.

The excess demand notion of price determination is perhaps more consistent with quarterly or monthly observations than the price dependent approach outlined above, since the excess demand notion provides for a disequilibrium framework, whereas the other notion is an empirical implementation of a static equilibrium model. As suggested, stocks can fluctuate considerably in the short run. Price behavior for such situations might be modeled as follows. Short-run farm level demand is determined by the derived demand from the Cobb-Douglas function, or

$$(17) \quad F^d = \alpha Pp/f,$$

while the farm level supply again is given or at least is highly inelastic. Stocks of F are residually determined by the difference between supply and demand for F. The demand for F is driven by the retail demand for P in equation (17), which for this framework would be fit as a standard quantity dependent demand curve, or $P^d = f\{p, z\}$. Hence, in a model of this type, the long-run price behavior would be quite similar to that outlined above. If retail demand shifts as a result of, say, a change in income, farm level demand also rises, perhaps with some small lag. With supply unchanged (no prices have changed), stocks fall, driving up the farm price. This price increase is in time passed on to the retail level through the margin equation. This increased price results in a decrease in demand, which again is passed through the system in the same manner as the original shift.

Discussion

Stanley R. Johnson

It seems apparent and is well argued by Fox (1973) in a report to the Council of Economic Advisors and the authors of the three papers for this session that public and private economic agents are requiring increasingly integrated and complex models of the agricultural sector for forecasting and decision purposes. Recognition of this unfulfilled demand for modeling of the agricultural sector raises a number of questions that are useful to keep in mind while evaluating the papers of Chen, Roop and Zeitner, and Heien. They are: why is the profession just getting around to formulating, estimating, and implementing such models? What factors have held back the development of these models and can they be identified? Have the authors of these papers addressed and resolved the issues raised by the first two questions?

The answer to the first of the questions can be viewed both positively and negatively. On the positive side, the increased role of government in the agricultural sector and in import and export markets, the increased sophistication of agents operating in the sector, increased flows of information into and within the sector, and finally the complexity and timing problems brought about by more freely flowing resources and added specialization all argue for the development and use of more comprehensive models. On the negative side, the "failures" of past attempts may account for the lag in applying widely known modeling techniques to the agricultural sector. In retrospect, it is apparent that the initial econometric models of the agricultural sector (e.g., Fox (1965), Cromarty) were oversold not so much by their builders but by those applying the methods and concepts that they embodied. One of the peculiarities of the agricultural sector is the high proportion of the variation in endogenous variables that is conditioned on exogenous variables that are difficult to project. As will be subsequently apparent, the overselling of the earlier sectoral models and some shortcomings of the present efforts have resulted from a lack of careful attention to this simple factor in model evaluation. Answers to the latter two questions are, in fact, the subject of the remainder of the discussion and, to anticipate the conclusion, they are qualified yeses.

At a general level, problems raised by attempts to construct these "second generation" models of the agricultural sector are several-fold. Specifically, for evaluating these models it seems reasonable to ask: (*a*) how large and complex should the models be? (*b*) what purposes or functions are served by increasing the complexity and size of the models? (*c*) are the objectives of the potential clients sufficiently similar to make one or a limited number of large-scale sectoral models adequate? (*d*) is the theory adequate to support the specification of these sectoral models? (*e*) are available data sources being used to advantage? (*f*) are the estimation procedures employed making good use of the sample and prior information? (*g*) are the models validated using methods that take best advantage of the theory, previous empirical work, and data? (*h*) is structural change sufficiently accommodated so that models are not highly specialized? (*i*) is there provision for updating the models in a systematic manner? and (*j*) finally, are policy and forecasting exercises being conducted so as to fully exploit the information contained in the models? General comments on these questions, although unduly brief, can provide a useful basis for evaluating the papers.

Regarding questions (*a*) and (*b*), both Chen and Roop and Zeitner have identified forecasting and policy needs but have omitted an important step in the process of rationalizing their larger or more integrated models as superior to existing constructs. Suppose it is agreed that the purpose of such models is to reduce the unexplained variation in an expanded set of exogenous variables. Whether this explanation should be structur-

Stanley R. Johnson is a professor of economics and agricultural economics, University of Missouri-Columbia.

ally oriented or not is left open. What must be shown is that the models link the endogenous to exogenous variables that have substantially less unpredictable variation. Otherwise, the structures have provided little for forecasting and prediction. If the variation in the endogenous and uncontrolled exogenous variables is about the same and the exogenous variables cannot be accurately projected then the structural model is of little value for forecasting purposes (Chow). As the simulations of Chen and Roop and Zeitner are based on assumed values for exogenous variables that would appear difficult to project, they may significantly misrepresent the usefulness of the models for forecasting and as well the claimed validity of the structures for applied policy analysis.

The problem of developing models that can be specialized for a number of diverse purposes deserves more attention than is given in the papers. From a mechanical viewpoint, this task is more straightforward for linear than for nonlinear and complex constructs of the type proposed by Chen and Roop and Zeitner. In this more general context, the idea of building models of the models, albeit a bit esoteric, may be useful. With such a conceptual framework, processes of specializing multipurpose models can become more formalized. In particular, for question (*c*) the same approaches can be applied in the context of specializing the complex models as are used in structuring the relationship between the model and sector. In the systems vernacular, models of systems or sectors are themselves systems. Approaches to their study can thus follow similar lines of inquiry.

Regarding question (*d*), i.e., the theory, there are useful developments that have occurred since the "first generation" models of Fox (1965) and Cromarty. In fact, Heien's paper seems to address this point. His suggestions for applying mixed demand systems rationalized on the basis of inverse utility functions and behaviorally determined storage components exemplify areas in which the theory has developed potential for additionally structuring sectoral models. Uncertainty and risk (Just), price expectations formulations versus observed futures prices, firm dynamics (Lucas), and dynamic consumer behavior (Philps) are additional areas in which the developments in theory seem not to have been advantageously used in providing structure for econometric models of the agricultural sector. Finally, for the linkages between the agricultural sector and economy, it is not apparent that much progress has been made. Providing these links with a series of identities is possible and done by Chen and Roop and Zeitner, but there must be more to the connection between economic sectors of an economy. Much the same is true of the provision for imports and exports. For the latter the lack of a more elaborate structure leaves as exogenous variables ones that have proved very difficult to project.

On the use of the data (question (*e*)), the authors of the two applied papers have been disappointingly unimaginative. In fact, in both papers much is made of the models being developed so as not to require data unavailable in generally known sources. Prior information, subjective or not, weighting observations, and combinations of time series and cross section and annual and quarterly series are all possibilities for gains in information to be captured in the estimated sectoral models. For example, the wealth of experimental data on crop production could support much more ambitious structures for relating weather variables to supply response (McQuigg). The practical objectives of both models to an extent explain this conservative treatment of the data. Apparently, some improvements in model quality can be obtained by working these alternative data sources. As well, such activities provide information on the potential value of additional but unavailable quarterly series.

Estimation procedures used by Chen, Roop and Zeitner, and Heien are not the most sophisticated. The arguments made for the use of single-equation ordinary least squares procedures are, however, for the present compelling; that is, the authors have decided to use their scarce resources for model construction and data assembly rather than estimation, which is consistent with the observation that the major gains to be made in sectoral modeling are in specification. When the anticipated returns to specification diminish, applications of improved estimation methods should be explored for their contribution to model performance. Among those not presently being applied, the biased estimation methods (Judge) and, of course, simultaneous equations methods seem most promising.

Simulation and/or experimentation with

the models is usually involved in both validation (question (*g*)) exercises and in forecasting and policy analysis (question (*j*)). Here, the standards in most applied modeling work in agricultural economics and not just those of Chen and Roop and Zeitner are notably lacking. Moreover, the procedures tend to be mechanically applied and not systematically evaluated (Rausser and Johnson). Weakness of the mean square error of forecast is an obvious case in point. Presumably this statistic is useful in evaluating the model for forecasting, but is the forecaster ever in the position to know the future values of exogenous variables with certainty? The answer is, of course, no. Although the test is of some use for observations on the structure, it can lead to undue enthusiasm about the validity of models and their potential value in a forecasting context.

Finally, there are considerations of structural changes (question (*h*)) and updating (question (*i*)), where there is ample room for improving the current sectoral models. Available results making the provision for variational parameters (Rosenberg), updating (Chow), and more flexible tests for structural change (Singh et al.) are readily applicable in the context of the presently specified sectoral models. These sectoral models are obviously nothing more than partial reduced forms for highly complex economic systems. Accordingly, it is important to specify them so that they can be continually revised to comply with information contained in most recent observations generated by the agricultural sector.

More specialized observations on the papers can also be made. The model presented by Chen is impressive in terms of its sheer size. Although a full development of the specification was not (and given space limitations could not have been) available in the paper, the summary information given shows that the model is producing at least intuitively acceptable results in some areas. The care and effort involved this process should not be over looked or undervalued. What has been provided is a workable quarterly econometric model of the agricultural sector that is highly disaggregated and can be integrated with the Wharton model of the general economy.

Specification and estimation procedures used in the model are standard or not significantly in advance of those employed by Fox over ten years ago. As a consequence, there is room for improvement of the model in each of the aspects suggested by aforementioned questions. For example, Chen cites Popkins' work on average prediction errors but does not demonstrate that his model moves toward their reduction in a systematic way. Almon lags are employed instead of time structures, which might be argued on a more sound theoretical basis. Linkages to general economy differ from those of Roop and Zeitner but are similar in being largely based on a set of accounting-type identities. Data are limited to those available on a routine basis, and little attention is given the problems of updating and structural change. The latter problems are, however, implicitly involved in the choice of the length of the data series to be used in estimating and testing the model. More positively, the linkages between subsectors, their commodity orientation, and the inclusion of climatic variables in the supply equations all speak well for a keen insights as to the workings of the agricultural sector.

The paper by Roop and Zeitner is more a progress report than a completed research project. A sectoral model, which is much more limited than that of Chen and does not perform well on a satellite basis even in limited validation exercises, is specified and then introduced into the Wharton model of the general economy. The linkage to the general economy model is again accomplished by a system of identities decomposing the aggregates in the present version of the agricultural sector. While the problem to which the paper is addressed is one that should receive attention and, in defense of the authors, is quite difficult, it is only fair to say that there is not evidence of much progress. A sectoral model that performed more acceptably on a satellite basis could have enhanced the value of the results of its integration with the model of the general economy.

Heien's paper is interesting in that it seems to be trying to get at the problem of specifying sectoral or commodity models to take more advantage of the available theory. As one who has had a hand in constructing the large-scale Commodity Economics Division/Economic Research Service cross-commodity agricultural sectoral model, his paper can be construed as evidencing a dissatisfaction with the standard structural specification. The concern with the treatment of stocks is

justified, and the approach providing a behaviorally enriched structure for explaining stocks holding is promising. What it suggests, however, is the need for more fully exploiting the results from dynamic models. The production function approach to relating retail and farm demands is not novel but is very adeptly explored for its implications in price relationships. As already indicated, the comments on mixed demand functions should receive substantial attention. They provide a consistent theoretical basis for formulations of demand functions that in the past have been specified by data dredging. Finally, the reference to Fisher and casual structures may need further elaboration. Although the principle is of use, the period of observation and level of aggregation for sectoral models make the result more of aesthetic than practical value.

In summary, it is encouraging to observe and be a part of the rekindling of interest in sectoral econometric models. The general and specialized comments pointing up the limitations of these papers should not be taken to be reflections on the work of the authors but instead to be encouraging possibilities for progress. These papers have provided a useful basis from which to proceed in improving the second generation sectoral models.

Agricultural Sector Models and Their Interface with the General Economy: Discussion

Richard E. Just

Chen points out that macroeconometric forecasters have done very poorly in predicting inflation rates, etc., for the general economy because they have failed to predict changes in their exogenous prices, many of which pertain to the agricultural sector. However, agricultural forecasters have also done very poorly in predicting the recent large variations in agricultural prices, and again the reasons lie in the lack of inclusion or difficulty in prediction of exogenous variables, some of which pertain to the general economy. Thus, both general and agricultural forecasters may benefit by pooling their models.

In a sense, the above arguments indicate that the predictive power of econometric models may be increased by increasing endogeneity. The notion is plausible because, as exogenous variables are converted to endogenous ones, the econometrician is forced to identify more basic underlying forces, which may lead to more useful predictions. This argument further suggests that the dynamic predictive performance of an econometric model in tracking certain variables should be evaluated not only in terms of the standard statistics, such as the root-mean-square error, but also according to the degree of endogeneity of the model from which they are generated. If one continually "plugs in" values of a closely related but simultaneously determined variable throughout the period of simulation for another variable, then the predictive performance should obviously be much better than if closely related variables are also determined endogenously. The latter approach is also often more sensible for predictive purposes, since measurements for simultaneously determined variables are not available in applied forecasting situations.

Richard E. Just is an assistant professor in the Department of Agricultural and Resource Economics, University of California, Berkeley.

Giannini Foundation Paper No. 429.

Before discussing the three papers of this session in this context, it is necessary to consider first what is an appropriate degree of endogeneity? Which variables in the general economy are determined simultaneously with or as a result of variables in the agricultural economy and vice versa? How important are these simultaneous or feedback relationships?

Interaction Between the Farm and Nonfarm Sectors

The interface between the agricultural sector and the general economy includes at least three classes of relationships: (*a*) the interaction of general price and income levels, agricultural marketing costs, and agricultural prices in domestic demand for agricultural products; (*b*) the interaction of agricultural input markets, which are influenced by other economic sectors, with the supply side of the agricultural sector; and (*c*) the interaction of international trade in agricultural and nonagricultural goods in determining trade balances, exchange rates, and export demand. Traditionally, agricultural sector models have emphasized mainly the first class of relationships and to a limited extent the second. The third class of relationships has been almost universally ignored.

The paper by Heien, which provides a nice summary of many classical causal and theoretical arguments in agricultural models, typifies the traditional approach (at least in those parts of his paper that deal with the interface of agricultural and general econometric models). General price and income levels and marketing costs are considered, but the supply and trade interfaces with the general economy are disregarded. The degree of endogeneity in the econometric models

produced by Heien is, indeed, very low.[1] For example, the farm-retail price spread for hogs and cattle is explained by using retail price as an exogenous variable.[2] Economic theory, however, indicates a high degree of simultaneity between farm and retail prices, and both can easily be treated endogenously in the same model. In his later regressions of retail beef, pork, and chicken prices on consumption of beef, pork, and chicken (Heien, table 1), a great deal more endogeneity is possible and perhaps necessary. Within the mixed demand system approach Heien uses, the specifications of his equations imply that consumption of all three commodities are determined prior to the corresponding prices. This possibility certainly seems unlikely, and exactly the reverse seems to hold on a day-to-day basis in grocery stores.

Turning to the Roop and Zeitner paper, one finds the second class of interface relationships relating to supply of agricultural inputs is also included. Hence, a feedback relationship is completed by linking both the input and output sides of the agricultural sector to the Wharton Mark IV econometric model of the general economy. However, the third class of interface relationships relating to international trade is absent. In fact, agricultural exports are apparently not considered endogenously by Roop and Zeitner at all. Such a practice may have been acceptable prior to the 1970s, but recent events too clearly point to the importance of trade and export demand in agricultural price determination. Although Roop and Zeitner's discussion suggests that "farm prices received enter directly into the determination of the unit value index of food exports," recent developments imply that a more likely possibility is exactly the opposite—export demand and prices have been a major determinant of farm prices received or the two are determined simultaneously. Roop and Zeitner, in fact, admit their lack of confidence "that the important interactions between the agricultural sector and the macroeconomy are being captured."

Roop and Zeitner conclude that agriculture "is one of the relatively smaller sectors of the total economy." If this is true, then one can argue that there is no simultaneity or feedback between agriculture and the general economy; hence, an interface is only important from the standpoint of including general economic variables exogenously in the agriculture sector. Both of the other papers in this session argue that this is not true and that agriculture does have an important impact on the general economy. Based on their arguments and the ones developed below, one must at least conclude that Roop and Zeitner's assertion is unwarranted, since their model specification precludes many of the economic relationships that lead to a strong impact of agriculture on the general economy.

Interaction of Agricultural and Nonagricultural Sectors Through Trade

Before proceeding further, a brief review of some of the events of the early 1970s may be useful. In this context, one can suggest ways in which agricultural, as well as general econometric models, have tended to be inadequate, especially in the interface.

Never before has this country experienced the kind of instability, in both agricultural and nonagricultural sectors, that it has in the last five years. Prices of some agricultural commodities like wheat, corn, and soybeans have more than tripled from 1971 to 1974 and have since fallen by about half that amount (Commodity Research Bureau). This tremendous volatility in U.S. agriculture has almost certainly been tied to international trade, as evidenced by the large increase in Soviet demand for U.S. grain. Initially, these huge price increases were attributed to production shortfalls and rising affluency in the world as a whole and, particularly, in the Soviet Union. But later Schuh advanced the hypothesis that currency realignment (exchange rate) was largely responsible for increased U.S. grain demand. Certainly, both variables (prices and exchange rates) made unprecedented movements almost simultaneously. The U.S. exchange rate (dollars per special drawing right [SDR]), which had been stable for twenty years, increased by about 25% from 1971 to 1974 and then declined again by about 10% (International Monetary

[1] I recognize that Heien may be merely intending to suggest functional forms, which could be imbedded in larger econometric models with greater endogeneity.

[2] One must also question this procedure on grounds of econometric theory since, if retail price is stochastic, the regression disturbance would be correlated with the independent variable, retail price. In this case, Heien's estimation methods produce biased and inconsistent estimators.

Fund). Schuh further argued that "exchange rate has been an important omitted variable" in U.S. agriculture models (p. 11). His hypothesis has since been tested in an econometric model for U.S. wheat specifically designed for that purpose, and the results overwhelmingly support Schuh's arguments rather than the production or income explanations (Fletcher and Just).[3] The exchange rates were treated exogenously in carrying out this test.

In the context of this discussion, the Chen paper is to be commended. He has developed a model that considers all three classes of interface relationships with the general economy. Both input and output linkages to the agricultural sector are provided, but also the impact of exchange rates enters in export demand equations for agricultural crops. Furthermore, much greater commodity detail is provided, the simultaneity within agriculture is much more explicitly included, the interaction of the feed and livestock sectors is clearly indicated, and government program variables are included in more detail and with more usefulness for policy-making purposes. Chen's arguments for commodity and intertemporal disaggregation are indeed sensible. The Roop and Zeitner paper is evidence supporting Chen's statement that "because of the gap existing between the complexities of farm commodity markets and the simplified nature of the agricultural sector specification in macromodels, little can be expected." Even in a model with much greater endogeneity, Chen's root-mean-square errors are generally lower than Roop and Zeitner's.

In view of the title of this session, however, it is appropriate to consider yet a further generalization in the interface of agricultural and general models. The three agricultural commodities mentioned above, for which prices more than tripled (while exports soared), represented three of the five most important commodities (in value terms) in U.S. international trade as of 1974 (Commodity Research Bureau). Furthermore, these three commodities are almost exclusively export items while the other two commodities (crude petroleum and iron-steel) were primarily import items. Of course, trade theory would indicate that when major export items are rapidly increasing in value, *ceteris paribus*, an extreme pressure is placed on trade balances, and eventually exchange rates must be adjusted to alleviate the pressure. As exchange rates are adjusted, domestic prices of many other internationally traded items, such as imported automobiles, also begin to change. Hence, the recent large variations in agricultural exports may have played a major role in the high rate of inflation in the general economy not just through the resulting high domestic food prices but through the international trade interface with the general economy. For a possible example, following roughly the same pattern as agricultural trade and general exchange rates, some steel prices more than quadrupled from 1971 to 1974 and then declined to about twice their 1971 levels (Commodity Research Bureau). This casual evidence is not at all conclusive. The true causal relationships may run in either direction or simultaneously in both directions. But at least these arguments suggest the possibility of some interesting and badly needed experiments relating to the interface of agricultural and general econometric models and the importance of agriculture in determining U.S. trade balances and exchange rates.

U.S. exchange rates have now been deregulated for more than two years, and they have been to some extent determined by trade conditions since 1971, when exchange rates began responding to balance-of-trade pressures. It seems that an endogenization of exchange rates in agricultural models or in the overall models in which they are imbedded is now appropriate, particularly given the importance of agricultural commodities in U.S. trade. But such a step requires that we go far beyond the usual level of interfacing agriculture with the general economy. Appropriate possibilities must also be allowed for interaction of the agricultural sector with other commodities not only domestically but also in determining trade balances and ex-

[3] Although there have been several attempts to show that exchange rates cannot possibly explain more than about a 25% movement in prices because exchange rates only moved by about 25%, such conclusions are not warranted in a more general model. If one considers that currency realignment is more closely akin to changing national income (e.g., changing purchasing power for all traded goods) rather than a simple price change for the commodity of interest, then in a model with several commodities both real price and quantity demanded for import (of a single good) may increase simultaneously purely as a result of exchange rate adjustment. Since this argument will be a topic of discussion in another paper, it will not be pursued further here. Even though Chen considers exchange rates, his model does not allow this possibility since exchange rates are used only to modify the price of the specific good(s) in question.

change rates, as well as the related feedback impact of exchange rates on export demand.

Research on the Economics of Household Consumption Behavior
(Rueben Buse, University of Wisconsin, Chairman)

Cross-Section Application of Linear Expenditure Systems: Responses to Sociodemographic Effects

Howard Howe

Analysis of consumption allocation with expenditure systems is well known in aggregate, time-series applications. Yet, until recently, studies of individual household behavior have not generally brought available demand theory to bear on the empirical estimates. Pollak and Wales cited two advantages of using complete demand systems for the study of demographic effects on consumption. Demand systems incorporate the budget constraint into the analysis and permit the separation of demographic effects from own- and cross-price effects as well as from income effects. Unless these effects are separated, the demographic effects estimated with one set of prices cannot be presumed to apply in a different price situation.

This paper discusses the interpretation of linear Engel curves as reduced forms of the linear expenditure system (LES) and the extended linear expenditure system (ELES). Parameters of these systems can be made functions of the sociodemographic characteristics of the household. With constant prices, the marginal budget shares in the LES are identified, but the subsistence expenditures are not. The ELES, which uses income in place of total expenditure, is exactly identified; all its parameters can be estimated by indirect least squares. Subject to the assumption of additive separability underlying the LES and the savings behavior implicit in the ELES, price effects can be estimated with data from a single cross section.

Howard Howe is an economist in the International Finance Division, Board of Governors of the Federal Reserve System.

The views expressed herein are solely those of the author and do not necessarily represent the views of the Federal Reserve System. Richard Berner and Philip Musgrove made valuable comments on an earlier draft of this paper.

Linear Expenditure System

Properties

The demand functions of the LES can be written

$$(1) \qquad x_{ih} = b_i + \frac{a_i}{p_i}\left(\mu_h - \sum_{k=1}^{n} p_k b_k\right) \quad \text{for } i = 1, \ldots, n,$$

where x_i and p_i are the quantity and price, respectively, of good i, and μ_h is the total expenditure of household h. Klein and Rubin developed the LES as the most general linear formulation in prices and income satisfying homogeneity, the budget constraint, and Slutsky symmetry. These demand functions represent the utility function

$$(2) \quad U(X) = \sum_{k=1}^{n} a_k \ln(x_k - b_k), \qquad a_i > 0, \sum a_k = 1, x_i - b_i > 0.$$

The a_i's are marginal budget shares, and the b_i's have been interpreted as a "necessary" or "committed" set of goods. Pollak cautioned, however, that strict interpretation of b_i as a necessary level of consumption could be misleading because b_i can take on negative values. The utility function is defined wherever $x_i - b_i$ is positive. The admission of $b_i < 0$ permits price-elastic goods.

The Stone-Geary utility function, as equa-

tion (2) is known, underlying the LES is additive and nonhomothetic. The additivity permits price responses to be expressed in terms of the subsistence quantities (or expenditures). The nonhomotheticity introduced by the subsistence quantities allows the LES to exhibit nonunitary expenditure elasticities.

Sociodemographic Effects

In cross-section studies, the sample is often subclassified by sociodemographic characteristics of the household to reduce unexplained variation in expenditure behavior, and Engel curves are estimated separately for these subsamples. Another means of taking sociodemographic effects into account is to postulate that parameters of the expenditure system are functions of household characteristics.[1] Pollak and Wales have described this procedure as "translating" the demand system.

The "subsistence quantity" of the LES (b_i) can be made an explicit function of the sociodemographic characteristics of the household such as age, education, occupation, number of members, etc. For simplicity, b_i is postulated to be a linear combination of these effects. Let

$$(3) \qquad b_{ih} = \sum_{g=1}^{m} c_{ig} z_{gh},$$

where c_{ig} is the effect of the gth characteristic on the subsistence quantity for good i and z_{gh} is either a dummy variable or a quantitative variable.

In principle, the marginal budget shares (a_i) could also be made functions of household characteristics: $a_{ih} = \sum_{g=1}^{m} \alpha_{ih} z_{gh}$. This generalization complicates the formulation because the LES requires $\sum a_k = 1$. The marginal budget shares would have to be divided by $\sum_{k=1}^{n} \sum_{g=1}^{m} \alpha_{kg} z_{gh}$ because there is no single scale factor that could be applied across all observations. In the studies reported here, a_i was treated as constant across households; only b_i was made a function of household size.

[1] Barten incorporated household composition effects using specific adult equivalent scales. Muellbauer expanded this approach using the indirect utility function. When considering the LES, Muellbauer obtained the same result as equation (5).

Expenditure Equations and Engel Curves

In a single cross section, it is assumed that all households face identical prices. The demand functions, equation (1), can be written in expenditure form

$$(4) \quad p_i x_{ih} \equiv e_{ih} = p_i b_{ih} + a_i(\mu_h - \sum_{k=1}^{n} b_{kh} p_k) \qquad \text{for } i = 1, 2, \ldots, n,$$

where the subscript h on b_i indicates that subsistence quantities now vary across households. Introducing equation (3) and defining $\gamma_{ig} \equiv p_i c_{ig}$, the expenditure equation becomes

$$(5) \qquad e_{ih} = \sum_{g=1}^{m} \gamma_{ig} z_{gh} + a_i(\mu_h - \sum_{k=1}^{n} \sum_{g=1}^{m} \gamma_{kg} z_{gh}),$$

where γ_{ig} is the value (at sample prices) of the gth characteristic's contribution to the subsistence expenditure of good i.

The reduced form of equation (5) is a linear Engel curve

$$(6) \qquad e_{ih} = \sum_{g=1}^{m} \delta_{ig} z_{gh} + a_i \mu_h,$$

where, by comparison with equation (5), δ_{ig} is implicitly defined as

$$(7) \qquad \delta_{ig} \equiv \gamma_{ig} - a_i \sum_{k=1}^{n} \gamma_{kg}.$$

As evident in equation (6), the marginal budget shares are all identified. The subsistence expenditures γ_{ig} cannot be recovered from the δ_{ig} because the system is underidentified by degree 1. Additional information or restrictions are required to permit identification of the γ_{ig} and thereby the inference of price effects.

Extended Linear Expenditure System

Lluch developed the ELES from an intertemporal maximization of the Stone-Geary utility function, equation (2) (1973). The ELES employs (a concept of permanent) income as the explanatory variable and incorporates an

aggregate consumption function. The typical ELES expenditure equation is written

$$(8)\quad e_{ih} = p_i b_{ih} + ma_i(\zeta_h - \sum_{k=1}^{n} p_k b_{kh}) \qquad \text{for } i = 1, \ldots, n,$$

where m is the marginal propensity to consume and ζ is permanent income.

The ELES is a particularly useful generalization of the LES in cross-section applications in that the independence of income from the expenditure error terms overcomes the least-squares bias encountered using total expenditure and that the ELES permits indirect least-squares estimation of all parameters since it is exactly identified.[2] The ELES can be developed from an atemporal utility maximization by treating saving as the $(n + 1)$th commodity, with $b_{n+1} = 0$ (Howe 1975). This a priori specification of one of the b's identifies the remaining subsistence expenditures in the absence of price variation.

The alternative development of the ELES can be repeated using current income (y) in the budget constraint instead of permanent income (ζ). In this case saving is out of current income, and m becomes the marginal propensity to consume current income. Using the same formulation for modifying the subsistence expenditures as with the LES, equation (3) can be substituted into equation (8) to obtain ELES functions reflecting the sociodemographic characteristics of the household. The current income version is

$$(9)\quad e_{ih} = \sum_{g=1}^{m} \gamma_{ig} z_{gh} + ma_i(y_h - \sum_{k=1}^{n} \sum_{g=1}^{m} \gamma_{kg} z_{gh}).$$

The reduced form of equation (9) is an Engel curve based on income

$$(10)\quad e_{ih} = \sum_{g=1}^{m} \Delta_{ig} z_{gh} + \eta_i y_h.$$

The marginal propensity to consume (m) equals $\sum \eta_k$. The marginal budget shares are then obtained from $a_i = \eta_i/m$. The γ's are identified from the Δ_{ig} and η_i.

The γ_{ig} identified in this way are subsistence expenditures at sample prices rather than the subsistence quantities themselves of equation (3). Strictly speaking, the c_{ig} that would appear in the structural ELES equation (9) are not identified. As Powell pointed out, measurements on p_i at the time of the sample are sufficient to identify the quantities. Price elasticities are readily expressed in terms of the subsistence expenditure; quantities are not required to evaluate price responses.[3]

Cross-section Estimates of Linear Systems

Prior to the introduction of the ELES, Betancourt applied the labor-leisure choice and wage rate information to the LES to estimate total subsistence expenditure and thereby identify all parameters (1971). Belandria employed the LES and the ELES to analyze cross-section household consumption data for three Venezuelan cities. He showed that the LES is underidentified where prices are constant over the sample and that the ELES is identified under the same conditions. Belandria treated the parameters of the expenditure systems as constant across households. Subsequently, Powell systematized Belandria's results on cross-section application and integrated them with new results on large sample biases in LES estimates.

In the following review of LES and ELES cross-section applications, the first two sets of studies translate the demand system with respect to household size or composition. The third group of studies follows the more conventional procedure of estimating the systems separately for demographically similar subsamples.

Estimates of Household Composition Effects

In an application of LES and ELES to Colombian cross-section data for 1967–68, Howe emphasized the effects of household composition on expenditure (1974). Following equation (3), the subsistence quantities

[2] Transitory components of current income could be correlated with the error terms of certain expenditure items. The use of normal income as a function of socioeconomic variables amounts to an instrumental variables procedure and results in unbiased estimates.

[3] The own-price elasticity can be expressed as $\epsilon_i = (p_i b_i/p_i x_i) \cdot (1 - a_i)^{-1}$ and the cross-price elasticity can be written in the form $\epsilon_{ij} = -a_i(p_j b_j/p_i x_i)$.

were postulated to be linear combinations of the number of persons in each of three age classes: zero to seven years, eight to seventeen years, and over seventeen years, and z_1 was set to 1 to represent the head of the household.

Estimates of the ELES parameters of equation (9) were obtained by indirect least squares and compared for four cities. Table 1 presents ELES estimates (and their standard errors) for Bogotá. The estimates of the marginal budget shares and the marginal propensity to consume out of current income are reasonable. The negative values for $\hat{\gamma}_{ig}$ are not easily interpreted in terms of subsistence expenditure, but none of the negative values are significantly different from zero. Also, the income effects are estimated with much greater precision than the subsistence expenditures.

Interestingly, the significant subsistence expenditures are all for persons aged eight to seventeen years and over seventeen years. It could well be that, at this level of aggregation, children under seven years of age simply do not affect consumption allocation greatly or consistently enough across income levels to yield significant γ's. In interpreting the subsistence expenditure of the head of household, it is useful to recall its role as an intercept term; its insignificance could reflect the lack of a constant term (or nonlinearity near the origin). In retrospect, a better formulation for subsistence quantity could have been

$$b_{ih} = c_{io} + \sum_{g=1}^{3} c_{ig} z_{gh}, \tag{11}$$

where the head would be counted as a member of the over seventeen years class, and the intercept could be tested explicitly.

Table 1. ELES System Parameters, Bogotá

		Subsistence Expenditure ($\hat{\gamma}_{ig}$)[a]

Nutritional Information

Just as the a priori specification of $b_{n+1} = 0$ for saving permits identification of the ELES in the cross section, independent information on any other subsistence expenditure identifies the remaining γ's of the LES. The use of nutritional requirements to estimate subsistence expenditures on food was inspired by Orshansky's work on defining the poverty line in the United States.[4]

For the Colombian study, independent measures of the minimum cost diets necessary to maintain adequate nutrition for persons of various ages were obtained. Monetary values of the minimum cost diets at prices prevailing during the sample period were used as extraneous estimates of the subsistence expenditure for food.[5] The resulting LES estimates are presented in table 2.

The estimated marginal budget shares of the two systems are very close. The subsistence expenditures for ages eight to seventeen years and over seventeen groups are within two standard deviations of the $\hat{\gamma}$'s estimated with the ELES. The $\hat{\gamma}$'s for the head of household are very different, a result of the intercept problem discussed above. The $\hat{\gamma}$'s for children under seven years old are much larger than those in table 1.

The poor estimates of γ for children obtained with ELES are probably a result of very different expenditure responses to children across income strata. Use of dummies for socioeconomic stratum in equation (3) for intercept and interactive effects would be the next step in improving the estimates of γ with the ELES.

[4] In an attempt to count the number of persons living in poverty in the United States, Orshansky observed that "there is no generally accepted standard of adequacy for essentials of living except food" (p. 5). She then proceeded to use low-cost food plans of the U.S. Department of Agriculture as the minimum outlays necessary to maintain adequate nutrition. The food plans are tailored to the age-sex composition of the household.

[5] A poverty budget approach was also tested in the Colombian study. The poverty budget for the individual household was substituted for the "subsistence expenditure" $\sum \sum \gamma_{kg} z_{gh}$ in equation (5), thus identifying the individual γ_{ig}. However, the estimates of γ_{ig} for food were not constrained to equal the values of the minimum cost diets.

Table 2. LES System Parameters Identified with Extraneous Nutritional Information, Bogotá

		Subsistence Expenditure ($\hat{\gamma}_{i0}$)[a]			
	$\hat{a}_i$	P 0–7	P 8–17	P 17+	Head

Economies of Scale

The linearity assumption of equation (3) was relaxed by redefining z_{gh} as a dummy variable for each size of household from two members to eleven or more. Although this modification lost the distinction between children and adults, it allowed subsistence expenditure to vary nonlinearly with household size. The profiles of the $\hat{\gamma}$'s as a function of size exhibited puzzling declines at five, eight, and eleven or more members. For the subsistence interpretation of the γ's to hold, subsistence expenditure must at least be increasing with respect to size of household.

These anomolous results are probably due to the same lack of consideration of socioeconomic stratum that caused problems with the household composition effects. With further refinement, this procedure could be useful in studying economies of scale in household expenditure. Ferber and Musgrove plotted the general trend of these estimates of food and total subsistence expenditure by household size. They found elasticities of subsistence expenditure with respect to size close to 1.0 for the range three to eleven or more persons.

Other studies investigated household size effects in translated linear expenditure systems without distinguishing household composition. Howe and Musgrove applied the ELES to four Latin American cities—Bogotá, Caracas, Guayaquil, and Lima—making only the distinction between large (five or more) and small households. The systems were also estimated separately by (*ex ante*) socioeconomic stratum (three strata approximating permanent income levels) and age of head (under forty-five years and over forty-five).

Committed expenditures (γ) tended to be larger for higher stratum households, showing that the γ more nearly represent subsistence needs at low incomes, while habits and expectations become more important as income rises. Younger households tended to have lower mean expenditures but higher committed spending. They behaved as if their notion of a minimally acceptable standard of living, or their expectations about future income, was higher than that of older households. The difference between γ_i (large) and γ_j (small) was greater for young than for old households.

Estimates of the marginal propensity to consume were extremely varied and often too low. They did not always decline as socioeconomic level went up, and they were often low for very low income households.

Separate estimation by stratum overcomes a major criticism of linear systems—the constancy of marginal budget shares across income levels, but it may complicate the study of household saving. If the share of income variation due to permanent income is not constant across strata, the bias in estimating the marginal propensity to consume due to transitory elements may be made worse when the sample is stratified (Howe and Musgrove). This problem was more serious with young than with old households.

Betancourt applied current income (1976) and permanent income (1973) versions of the ELES to Chilean data for 1964. He reformulated the ELES to use discrete time and a finite horizon and allowed subsistence expenditure to vary as a function of household size with an economies-of-scale effect. The ELES was then estimated separately by twelve subsamples (six age classes and urban-rural location). Shift dummy variables for occupation (also interpreted as socioeconomic class) were applied to income and household size.

Betancourt found that, although failure to control for socioeconomic stratum led to differences of less than 10% in the income-related estimates of ELES, differences of substantially greater than 10% resulted in the price-related ELES estimates (1976). Esti-

mates of the economies-of-scale parameter varied widely.

Pollak and Wales applied two cross-section data sets to obtain price variation for estimating the LES and a quadratic expenditure system. They used family expenditure data from the United Kingdom for 1966 and 1972. Mean consumption expenditures on three categories for twenty-nine cells of various income and family size classifications were combined with price indexes for the two periods. The subsistence quantities were translated as functions of the number of children in the household. The estimation employed the same methods used for time-series data with price variation. Although not the first to pool cross-section data, Pollak and Wales demonstrated that sufficient price variation existed in only two cross sections to permit identification of the parameters.[6]

Estimation by Subsample

In addition to the studies presented above that also incorporated variable subsistence expenditures, three recent cross-section studies investigated the influences of sociodemographic characteristics with separate estimates by subsample using constant subsistence expenditures. Lluch, Powell, and Williams (chaps. 5, 6, and 9) estimated the ELES for Korea, Mexico, and Yugoslavia.

For Korea, urban-rural differences in demand behavior were explored by estimating the ELES separately for urban and farm households. Per capita income and expenditure data from annual sample surveys were combined with consumer price indexes for each of these areas. Then urban cross-section data for 1971 were separated into six subsamples (salary and wage earners, young and old head of household, small and large household), and separate ELES estimates were obtained for each type of household. The authors show that for expenditures on nondurables, the cross-section data yielded disaggregated demand parameters and elasticities that, when averaged, were broadly consistent with time-series estimates.

For Mexico, separate ELES estimates were obtained for thirty-two subsamples (rural-urban location, socioeconomic class (3), large and small family, young and old head of household) of the population surveyed in 1968. The authors found that if the data were to be pooled for estimation, the model should allow for family size effects, the subsistence parameters should shift by socioeconomic class, and marginal budget shares should be allowed to vary with income. The first two modifications could be accomplished in a translated ELES using the form of equation (3).

Separate ELES estimates were applied to twelve subcells of Yugoslavian farm households separated by region and type of farm. Income levels varied substantially across these groups; mean income more than doubled from poorest to richest. Marginal budget shares showed little variation by income level. Although the farm households were reasonably homogeneous with respect to demand behavior, savings behavior was influenced by income level.

Income Concepts for the ELES

All of the results reported thus far proceeded from an ELES using current income. As developed theoretically, the ELES employs a concept of permanent income. In an attempt to develop a measure of permanent income, Belandria estimated relationships between current income and age, education, and occupation. The estimated coefficients were then used to impute expected or normal income for each household.

Howe employed the same procedure to generate a measure of normal income except that the log of income was used as the dependent variable (1974). Betancourt applied a method whereby the household in question is assumed to focus upon a similar household in the next highest age class to form an estimate of its permanent income (1973).

Howe found that although the normal income ELES provided superior estimates of the marginal propensity to consume for two of the four cities, the number of observations for which subsistence expenditure exceeded actual expenditure (a violation of the LES property, equation (2)) was much greater than with current income (1974, pp.201–13). Belandria and Betancourt also found that normal or permanent income produced significantly higher estimates of the γ's. Because the normal income procedures underestimate the variance of permanent income,

[6] Lluch used price variations among regions to estimate an LES with cross-section data from Spain (1971).

current income has been preferred for estimation of the ELES.

Conclusions

Modest success has been achieved in estimating price effects along with income and sociodemographic effects from cross-section data. Although such estimates are obtained at the cost of very restrictive assumptions, the results have often been reasonable enough to encourage further application to cross-section data. The ELES could prove particularly useful in developing economies where sufficiently long time-series data on the components of consumption are lacking.

Although the LES and ELES provide wide scope for analyzing a single cross-section of household data, some caveats are in order. Aside from the restrictiveness of the LES itself, the complications arising from transitory behavior in the cross section are considerable. Because of the severity of the assumptions, the ELES parameter estimates could be valid only locally. Care should be exercised in extrapolating the system far from the sample prices and incomes.

Both translated expenditure systems and separate systems by subsample are applicable to policy-oriented models. Since the translated models discussed here all varied subsistence expenditures while holding the MBS and MPC constant, estimation by subsample could be a useful first step in testing the validity of that assumption. A translated system is superior to a set of subsystems in that it imposes the budget constraint on the analysis of sociodemographic responses. A translated system requires that the changes in expenditure components in response to a change in household composition sum to zero if total expenditure remains constant.

In all of the studies reported here, separation into subsamples was employed to some extent. Even in the Colombian study, with the most extensively pooled model, estimation was separated by city. In most cases, all parameters of the system differed significantly by subsample.

A rule of thumb for applying demand systems to policy problems would be to incorporate the sociodemographic effects to be analyzed (age distribution, household size or composition, etc.) in the translation of the system and then to subdivide the sample by the other sociodemographic characteristics known to affect importantly the parameters of the system. In this way the restrictions of demand theory are imposed on the effects under study, while unexplained variation in expenditure behavior resulting from other sociodemographic differences is reduced. However, as found in Howe and Musgrove, stratification of the population may improve the expenditure functions but lead to unreliable descriptions of savings behavior. Another aspect of such a procedure requiring careful judgment is that the number of subclasses could proliferate to the point of making sample sizes too small and simulation of the full system unwieldly.

Household Consumption Behavior: Understanding, Measurement, and Applications in Policy-Oriented Research

Alden C. Manchester

I am interested in understanding consumer behavior for use in policy-oriented research. In pursuit of this goal, the possible assistance of theory to better understand consumer behavior is discussed, and empirical measurement of the parameters of consumer behavior is considered in relation to the needs of policy makers.

Theory and Its Uses

Phrases commonly used by economists often tell more about our intellectual habits than is realized. One such phrase is "received theory," which carries the connotation that theory has been received from on high, perhaps inscribed on a new tablet, and the empirical analyst merely takes the theory as provided and proceeds with his analysis. Such a practice is to be avoided in many cases but especially so in the area of household consumption behavior. The analyst should approach the choice of the theoretical constructs at least as carefully as he would the selection of statistical methodology, with due consideration for its effectiveness in the role contemplated.

Measures of what consumers do and of why they do those things are needed. The why's must be in terms of observable phenomena in order to be useful to the analyst, as theory that cannot be put into measurable forms is not useful.

The basic postulate of the economic theory of consumer behavior is that the individual maximizes the utility derived from the consumption of goods and services within a set of constraints imposed by prices and income.[1] The usefulness of this assumption as a basis for organizing the measurement process is somewhat limited since one is unable to suggest a basis for quantifying utility. This inability has one distinct advantage. Since there exists no principle comparable to the principle of profit maximization in firm theory, one is not distracted by the spurious intellectual appeal of the idea or led to the assumption that the rational economic man maximizes a measurable quantity, therefore proving any other behavior to be irrational and intellectually if not morally wrong. The hurdle that must be leaped to explain the tremendous variety in consumer behavior is not nearly as great as that encountered when dealing with firm behavior. It is easier to search for a theory that explains the nonconformity of consumers' behaviors under similar circumstances rather than one that asserts that they should conform. Consumers are no more optimizers or maximizers than are business firms. (This discussion is also in the spirit of Leibenstein.) To a very considerable extent, they are satisficers. Optimization is simply unworkable.

A further difficulty of conventional theory arises from the complication that the household is the consuming unit rather than the individual, which is the basis of the theory. While this probably does not create as much of a problem as the assumption that the entrepreneur is the business firm, even if the firm is General Motors, it is one more reason why a theory based on individual preferences is likely to be unsatisfactory.

Alden C. Manchester is a program leader in Consumer Economics and Demand Analysis, National Economic Analysis Division, Economic Research Service, U.S. Department of Agriculture.

The author is indebted, especially in the first section of this article, to Bryan J. Loasby for the inspiration provided by his article.

[1] Porter's point that the consumer maximizes net utility (net of the costs of information acquisition measured in utility terms) is appealing but leads no further in terms of empirically usable theory. It merely adds to the measurement problem.

The theory of consumer behavior is constructed in terms of equilibrium concepts, consisting largely of statics or comparative statics. With statistical and econometric investigations strongly conditioned by the theory, a high proportion assume that equilibrium is the general case and that departures from it are taken care of in the error term.

Equilibrium is much less commonly the case than many of us have assumed. For these purposes only major departures from equilibrium are discussed; otherwise, everyone is constantly in disequilibrium. The sources of disequilibrium can be conveniently grouped as economic and demographic. (I ignore for this purpose disequilibrium resulting from psychological sources, such as a major change in lifestyle and purchasing habits). Some of the major economic causes of disequilibrium include change of job, unemployment, reemployment, retirement, strike, purchase or sale of home, change in tenure status, and change of residence (moving). Major demographic changes include marriage, divorce, death in the family, birth, children leaving home, son or daughter off to college, and other relatives moving in or out.

Several recent investigations provide some indications of the incidence of these conditions that lead to disequilibrium. Buse and Salathe, working on a cooperative agreement with the Economic Research Service and using the 1960–61 Consumer Expenditures Survey, excluded 6,300 out of nearly 14,000 records in order to isolate an equilibrium set. They excluded the categories listed above as well as those with missing and obviously wrong data and certain categories that, while in equilibrium, are in a different one than the standard set of households. This last group includes those working without pay, families consisting of husband, wife, and other adults, those continuously retired, nonhousekeeping households, and those who rent rooms.

The University of Michigan study of income dynamics traced an original sample of 5,000 households for five years (Morgan). The changes in those households over the period were mind boggling.

It is obvious from these two studies that the incidence of disequilibrium is quite high and must become a major consideration in concepts and measurement. In measurement, it can be dealt with as Buse and Salathe have by separating out those in disequilibrium and treating them separately, expecting to find different relationships among the variables. Clearly, studies of the adjustment process itself are needed, which can only be done with longitudinal data such as that from Michigan (Benus, Kmenta, and Shapiro).

Applications

The reason for attempting to understand household consumption behavior to make measurement possible—over and above the scientific desire for pursuit of truth—is the application in further research. There are many different research environments. The ERS's interests are in the markets for agricultural products, primarily food and textiles. The demands for these products must be understood to be able to forecast future courses of prices under given (or forecast) supply conditions and to analyze the impacts of a wide variety of policy changes.

In this kind of analytical atmosphere, why are we interested in micro data such as that from cross-section or panel studies? Why are we not satisfied with the aggregate data available from the National Income Accounts, ERS per capita consumption data, and similar sources? The answer has dual roots. In the first place, we are always interested in better estimation of aggregate effects. The aggregates, even if they were perfectly measured, which they are not, mask many changes by the groups that make up the whole. Knowing how different groups within the population behave and the changing relative importance of those groups enables provision of better forecasts. Second, we are interested in distributional effects of economic developments and policy changes, which can be obtained only with disaggregated models.

Some reasons for differential behavior on the part of different groups in the population have already been touched on in the discussion of equilibrium. With appropriately disaggregated models and projections of demographic data, it would be possible to improve forecasts over those that assume average effects for all members of the population.

The basic question is how do households allocate their available resources among various expenditure categories? This is probably a bad way of expressing the question. It seems doubtful that most consumers engage in a process described by economists as

allocation of resources. But the use of the term resources has one clear advantage over using income. It avoids the implication that the expenditures of an individual household are limited by the size of current income. Clearly, the availability of credit and its use change the picture considerably.

What economists seek are the analytical links between the macro variables of the economy—income, price levels, population, and unemployment—and the demand for specific classes of agricultural products. Analyses using aggregate economic measures provide price and income elasticities and a few very crude measures of cross elasticities but not shifters for the demand functions relating to other variables, which are too often assumed away in the *ceteris paribus* assumptions.

The behavior to be understood is that of groups of households, not individuals. The advantage of having data for individual households is that one can search for groupings for which behavior is explainable.

Demographics

Demographic changes are some of the most significant and best documented in the U.S. society. While the approach to zero population growth is probably the most discussed, it is of less current importance than the very rapid change in household size in recent years. Average household size declined nearly 12% from 1960 to 1975 and over 6% from 1970 to 1975.

The growth in one- and two-person households is the most significant portion of this change. This has two major components: the increase in the elderly living alone and the increase in young people living separately from their parents. Both of these in part result from increasing incomes; both have some effect on food expenditures, since one- and two-person households tend to eat out more than larger households and since certain economies of scale in food purchasing and preparation are foregone.

Some preliminary exploration of the effects of demographic variables on aggregate at-home food expenditures has been undertaken (Manchester 1976). The effects of changes in prices, quantities, household composition, and the shift to more or less foods on per capita expenditures for at-home food were estimated for each year, 1960–74. While price changes were the most important, the effects of changes in household composition were more important than the effects of changes in quantity in half the years. Away-from-home food expenditures increased nearly 9% between 1960 and 1975 due solely to the increasing proportion of small households, if the relationships in the 1972–73 Consumer Expenditures Survey diary data are true (U.S Dep. Labor).

The changing age-sex distribution of the population may have greater effects than household size on consumption and demand. A major bulge—the result of the postwar baby boom—is working its way through the population. Since children, teenagers, and adults appear to have considerably different food needs and consumption habits, fairly marked effects have already been seen on the consumption of individual food products (Le Bovit, Schrimper). For a number of food groups, changes in household size and the age-sex distribution "explain" a significant portion of the changes in per capita consumption between 1965 and 1975.

Lifestyles and Attitudes

Changing lifestyles are less well documented than demographic changes for obvious reasons. Purchasing and consumption behavior is, of course, heavily conditioned by the common base of information and attitudes conveyed by the media, principally television. In a society with a dominant middle-class lifestyle, the potential utility of searching out differences in lifestyles as a classification variable in analyses of consumption and expenditure behavior seems small. On the other hand, changes in the dominant lifestyle over time have obvious effects on consumption behavior. The changes in the clothing market in recent years provide an excellent example. The boom in casual clothing reflects the same change in lifestyles as the rapid growth in fast food establishments.

Over time the attitudes and preferences of consumers change, and their purchase patterns reflect this. A major part of these changes occurs in response to the demand creation efforts of manufacturers of food products. The ubiquity of new product development among food manufacturers is well known and is not reiterated here. It is one of

those cases where it is easy to lose sight of the forest by concentrating on the trees. The overall effects of the introduction of new processed food products on purchase patterns tend to get exaggerated by too much concentration on the process. Despite what is known about the massive introduction of convenience foods since World War II, the overall effects on food consumption patterns are minimal. In the nearly two decades between 1952 and 1971, the share of highly manufactured products of total food consumption was virtually unchanged (Manchester 1973). The biggest changes in the whole picture were a sharp increase in fresh meat and a modest decline in fresh fruits and vegetables and eggs.

The dramatic price rises of 1973–75 brought about some marked changes in consumer attitudes and behavior. Consumers say, when surveyed, that they have made fairly significant changes in their purchasing patterns. When the data become available, it will be interesting to see how much change has come about in the aggregate purchase patterns. Whatever the magnitude of change in the last few years, the fundamental question is: will these changes persist as consumers adjust to the changed price levels?

Another significant change is the increase in working wives. This combines elements of demographic change, some change in lifestyles, and changes in attitudes. Cross-section survey data provide an excellent opportunity to analyze the impact of the working wife on expenditure patterns for food and other goods and services.

Kind of Income

The mix of income sources has changed fairly substantially during the postwar period, especially in the last fifteen years. The war on poverty brought a dramatic increase in the number and size of income assistance programs, making significant changes in the kinds of income available to households.

Different kinds of income have different effects on the ways that households use the financial resources available to them. The categorical programs, such as food stamps, have the most obvious effects. Others probably work more through the effect on uncertainty and the willingness to spend a larger proportion of current income and to commit more of anticipated income through the use of credit. The effects on food expenditures are probably mostly indirect through the impacts on other expenditures, but they are all a part of the question of how households allocate the resources available to them. Again, cross-section data provide an opportunity to improve understanding of the effects of different kinds of income on spending patterns.

Diet and Health

Health problems have marked impacts on food purchases. Over half the households in a national probability sample report one or more members with a health problem. Most common was overweight in 30% of the households, with allergies and high blood pressure each reported in about 20% of the households. For most health problems, 50% to 60% of the households had changed diet. This is a potential area for analysis of the effects on consumer purchase behavior. To the extent that health problems are associated with the changing age structure of the population, they are already at least partially covered by consideration of age itself. As new diet-health relationships are hypothesized or identified, impacts on other food groups may begin to be felt. As many other developments, it will be necessary to keep a sense of perspective. Cholesterol and eggs are a good example. Surely, some significant part of the long-term decline in egg consumption is due to changes in habits (lifestyles?) and not due entirely to cholesterol consciousness.

Quality, Services, and Prices

The goods and services for which expenditures are measured are interrelated, as each commodity or good purchased includes certain services and similarly, but not so commonly recognized, many services also include goods. For example, hospital charges include the cost of meals. In addition to variations in the services purchased along with the goods, there are variations in the physical characteristics of many goods that are often interpreted as quality differences. Many times the prices charged for goods include varying amounts for both services and quality differences.

Any data set involves the aggregation of

more than one item; otherwise, the 5,000 items in a typical supermarket would have to be analyzed separately. Whenever items are aggregated within a store and then across stores and cities, various goods, services, and qualities are combined. The necessity of such aggregation is not an excuse for ignoring its consequences.

A small amount of research has been done in looking at some of the variations in service, quality, and price (Houthakker; Manchester, Brown, and Jarvesoo). The basic hypothesis is that the price paid for a given item by an individual household is a measure of its demand for quality and services. In cross-section surveys where quantity data or price data are available, analyses of this type need to be carried out. Aside from the intrinsic interest in the question, separating the effect of quality and service from those of quantity changes will allow the analyst to use expenditure data as a proxy for quantity data with substantially more confidence in the results. As a practical matter, in most cases it is unknown what errors may be introduced into analyses by assuming that expenditures and quantities are identical.

Relevance to Policy Questions

Within the broad field of food and agricultural policy, the number of policy questions that call for analyses in which demand parameters are crucial is legion. No attempt is made here to compile a complete list.

Better estimates of price and income elasticities are needed. In order to derive them, measurements of what are called "shifters" arising out of demographic, economic, and lifestyle changes are needed, both for the aggregate and for significant subgroups of the population. Measurements of the time spans involved in the adjustment process are also required, so that the impacts of proposed policy changes over time can be estimated.

A major area of policy analysis in the ERS deals with changes in commodity programs for crops and milk and their impacts on farm prices, farm income, consumer prices, and government costs. These analyses require farm-level demand functions. Another area, which has been honored more in the breach than in the observance, is marketing services. Despite excellent work a number of years ago (Waldorf), analyses of the demand for processing and marketing services have been neglected. The substantial efforts devoted to measurement of price spreads have been complemented by relatively modest efforts at measurement of relationships between prices at various market levels (Sun, Barr and Blanciforti, Popkin, Manchester 1962).

A rapidly growing area in recent years has been impact analyses. Starting with environmental regulations on costs, prices, incomes, and related variables, this has grown into a major area. Inflationary impact statements are now required by a presidential executive order for a wide range of administrative actions. Several proposals are before the Congress to require cost-benefit analyses for every regulation issued by the Executive Branch and for every legislative proposal sent to Congress. If anything similar to these bills was to be passed, which is likely, the present cottage industry devoted to the preparation of impact statements would develop into a major employer and demander of supply and demand coefficients.

One area that is particularly demanding for good measurements of consumer demand behavior is the analysis of domestic food programs. The food stamp program, the school lunch program, and related food aid programs account for more than a half of the USDA's budget, yet the knowledge base for analyses of these programs is severely limited. Demand parameters relating specifically to food program participants are virtually nonexistent. Their development awaits provision of an adequate data base. Specific parameters that are badly needed include those relating participation in the food stamp program to eligibility.

Conclusion

To summarize, better demand parameters are needed for use in forecasting and policy analysis. The parameters available are unsatisfactory because current understanding of consumption behavior leaves much to be desired. This understanding fails the test of the marketplace because the theory available is imperfect, the means of converting theoretical constructs to observable (quantifiable) behavior is lacking, and the empirical analyses have concentrated on price, quantity, income, and population to the exclusion of

the many other variables that affect demand.

As I recall John Kenneth Galbraith said on a similar occasion, though it would probably not appear so to him, these are all important problems and I recognize that I should have given you the answers. However, you will have to be satisfied with understanding the problem.

Consumer Expenditure Survey, 1972–73: Processing and Dissemination

Stephen Baer

The Bureau of Labor Statistics (BLS) over the past eighteen months has been publishing tabulated results from the 1972–73 Consumer Expenditure Survey. This paper briefly describes the survey, reports on the status of the dissemination of data in publications and tapes, and discusses some of the factors research analysts must consider as they plan projects that make use of the data. A description of the survey is contained in an article by Carlson.

The Survey

The 1972–73 survey, the eighth in a series and the first in twelve years, is the only comprehensive source of detailed information on family expenditures and income related to socioeconomic and demographic characteristics of U.S. families. These data are also a primary source of information to update the expenditure weights and pricing samples leading to a revision of the *Consumer Price Index* (CPI). The revised CPI is planned for publication in April 1977. The July 1974 issue of the *Monthly Labor Review* contains an article on this subject by Shiskin.

The survey consists of two components, each with its own collection vehicle and sample: a diary or recordkeeping survey completed by respondents for two one-week periods and a quarterly interview panel survey in which families reported information to interviewers every three months over a fifteen-month period. The diary survey was conducted from July 1972 to June 1974. The quarterly interview survey was conducted for the calendar years 1972 and 1973.

The survey design was tailored so that information on larger expenditures was collected by interviewer-assisted periodic recall methods and information on frequently purchased less expensive items was collected by diary recordkeeping techniques. Furthermore, the interview design took account of the notion that some expenditures are easily recalled over long periods, while others are more accurately recalled only over short periods.

Although the diary was designed to obtain the detailed information on food purchases as well as housekeeping supplies, nonprescription drugs and medical supplies, and personal care products and services, respondents were requested to report all purchases made each week except those incurred while on trips.

The quarterly interview survey obtained detailed information on family income, changes in assets and liabilities, and major items of expense. Included was information on housing, utilities, house furnishings, housing repairs and maintenance, clothing, major and minor equipment items, auto purchases, leasing, and repairs, recreation, personal insurance, medical care, education, reading, tobacco, and miscellaneous expenses. Global estimates of food purchases both for at home consumption and at restaurants were also obtained. A comprehensive set of family characteristic information for each family supplemented the expenditure data in each survey component.

The diary sample was divided equally into fifty-two weekly subsamples for each of the twelve-month collection periods. This permitted an accounting for the seasonal nature of expenditures over time. The interview survey samples were initiated in the first calendar quarter of each year. Data collection was conducted over five quarters.

The 1972–73 survey was the first in which the Bureau of the Census took an active part in the collection of the data. The value of its participation is reflected in the cooperation

Stephen Baer is with the Bureau of Labor Statistics, U.S. Department of Labor.

rates attained. The first year diary survey experienced an 80% response rate, growing to 90% for the second year. Over 20,000 one-week diaries were completed each year. In both years of the quarterly interview survey, cooperation rates exceeded 90%, resulting in 10,000 completed questionnaires in each year.

In addition to the collection of data, the Census Bureau was responsible for field editing, quality control, diary coding, production of weights from BLS specifications, data keypunching, and certain computer edits including separation of consumption expenses from business expenses. Tapes of edited data by quarters were transmitted to the BLS at the conclusion of these activities.

Data Processing

The design of the survey has influenced the processing activities and plans for dissemination and creates the need for users to be familiar with concepts and definitions before applying the information to analytic uses. Data from the diary survey were coded by the Census Bureau field staff. Over 1,700 separate item codes were used. Consistency checks were performed to assure that characteristic codes for information such as age, sex, race, etc., were assigned. At the conclusion of data coding and review, information was keypunched and subjected to computer edit. Computer files of the survey information were produced and transmitted to the BLS, where the tapes were further screened for consistency and for valid codes.

The reliance on respondent-recorded entries in the diary led to the need for disaggregation of combined reports in that survey. In some cases, respondents did not supply sufficient detail necessary to meet desired specifications. Item allocation routines were developed by BLS to assign proportions of the value reported for a combined entry among the components of that entry. For the most part, these assignments were made using proportions derived from specific reports in the other completed diaries. For example, nonspecific reports of cheese purchases were allocated among soft or semisoft cheese, solid or hard cheese, or cheese spreads.

Initial pretabulations of data were produced by expenditure code to disclose extreme values. These were cross-referenced with the schedule reports, and updates were performed. Extreme values confirmed as correct were not adjusted. Because of the large volume of diary expenditure reports, only a limited number of tolerance updates could be carried out. These were sufficient to ensure the reasonableness of the resulting publication tables; however, users of final microdata tapes should be careful to inspect the values because of the possible existence of undetected keypunch errors.

Test tables of expenditure data classified by important family characteristics were produced, and separate frequency distributions of individual item codes by characteristics were run. The test tables were reviewed for reasonableness. The weighted frequency counts of socioeconomic characteristics were checked against comparably defined data from the Current Population Series reports (U.S. Dep. Commerce). These evaluations led to further correction of keypunch errors in the income data and program correction in the assignment of family characteristic codes.

The pretabulations were further reviewed for the statistical reliability of mean expenditures. This review helped to determine the level of detail for publication. In the publication tables, the number of sample families in certain columns and cells is small, since the tables present finely classified breakdowns of families and purchases. Column totals based on fewer than seventy sample families or cells containing fewer than five sample observations are likely to have large sampling errors. When these circumstances exist, they are referenced by footnotes to the tables.

Income data were carefully inspected for completeness. While no imputation was conducted, incomplete income reports were identified and coded. The value of income reports from major sources such as wages and salaries and income from profession, unincorporated business, or farm was cross-referenced with reports of weeks worked by each family member. Families were coded as incomplete reporters if the head reported weeks worked but failed to report income from such employment. For cases in which the family head did not work, the procedure was applied to the spouse or other family members. A number of diaries contained members, all of whom did not work during the income reference period. These, most typically, were small families with retired

heads. In such cases, incomplete income codes were assigned if families reported receiving pension, annuity, or social security income but did not provide dollar reports for these income items. Similarly, those families reporting no work experience but indicating receipt of nonemployment income such as welfare benefits or alimony payments were coded as incomplete income respondents if no values for such items were reported. Publication tables by income class contain a separate column of data for families defined as incomplete income reporters. These represent about 11% of the usable diaries. Apparently, many respondents who provided poor or no income data also provided scanty expenditure data.

The collection design for the quarterly interview component specified differing recall periods for various classes of items. Data on income, assets and liabilities, and housing expenditures were collected annually. Data on large expenditures such as major appliances were collected at six-month intervals. Frequently purchased items were collected each quarter. Some information for food and transportation services was obtained by weekly or monthly expense pattern estimates in selected quarters. Data for utilities were collected by quarter from reports on specific bills together with billing periods of reference. These collection procedures were designed to assist the respondents in supplying accurate reports but later introduced computational problems for data tabulations representing a uniform period.

The Census Bureau had the primary responsibility for initial processing of the interview survey data. The family characteristic components for each family record were screened for coding completeness. The expenditure data were subjected to computer adjustments to separate the business portions of expense entries from the consumption portion. These were most typically found in the housing, transportation, and trips components. Also, computer edits were performed to derive missing information in the liability section of the questionnaire. Furthermore, the Census Bureau supplied special nonresponse codes in expenditure fields for which purchases were indicated but no expenditure data were reported. This was possible because most expenditure entries were preceded by conditional yes-no questions. For example, in the collection of clothing data, respondents were first asked whether or not they incurred an expense for an item before being asked for the expense itself. A special nonresponse code was entered if the respondent reported making a purchase but failed to subsequently provide the cost.

Final tapes of the edited and coded data were then transmitted to the BLS. At this stage, special codes were created for data classification purposes. For example, family size codes were produced from the family member data. Programs were written to arrange the expenditure data into desired expenditure classes for publication. Tolerance listings were produced to expose keying errors or questionable reports of great magnitude. Because of the enormous volume of data, only limited tolerance error updates could be undertaken. These have helped to assure the reasonableness of published tabulations, but because not all extreme values were inspected errors may exist on the microdata tapes. Ultimate users of the tapes should carefully review the data for unusual reports.

Procedures similar to those performed for the diary were carried out for the coding of incomplete income reports in the interview. Only about 5% of the usable interview sample of families were identified as being incomplete income reporters. The difference between the 11% incidence of incomplete income reports in the diary and the 5% in the interview is most probably accounted for by the fact that the latter survey benefitted from interviewer rapport built up during the collection of less sensitive data over the four interview quarters prior to collection of income information. The diary, having a minimum of interviewer participation and a short collection period, was not so advantaged.

Data imputation routines were developed by BLS to account for missing expenditure entries using the special Census Bureau nonresponse codes. Regression testing yielded information on those characteristics most likely to explain expenditure behavior. The schedule returns were arrayed on a matrix defined by family income level, tenure arrangements, a family size-type variable, and a geographic variable. Schedules with missing expenditure entries were then subjected to a computer routine in which imputation values were obtained from similarly classified survey families reporting complete information. As might be expected, item nonresponse differed according to the sensitiveness of the

queries. The procedure was useful, but surprisingly few imputations were necessary.

The last major processing step for the interview survey was to convert the data obtained by the various recall collection periods to annual estimates. At the same time, estimates of sales taxes were produced for the expenditure items. This was an extensive and complicated program. At the conclusion of the data review and processing operations, a set of tabulations was produced that was reviewed for reasonableness and statistical reliability.

Dissemination of Results

To date, the Bureau of Labor Statistics has made data available in publications through the Consumer Expenditure Survey series of reports. Data from the diary component of the survey have been published for each twelve-month survey period in selected one-way classifications and cross-classifications of family characteristics. Broad classes of expenditures are shown in these tables. By early 1977 data from both years of the diary survey will be combined and published by family characteristics for the United States and each of four U.S. regions. These tables will present details within broad expenditure classes. The BLS also plans to publish expenditure variances, which can be associated with the magnitude of average expenditures for major consumption components and the number of families represented by the expenditure components.

Work is under way to produce a public-use tape of the detailed diary income and expenditure data in micro form. Included will be wide range of socio-economic characteristics for each diary record and those expenditures for which the diary was designed. Separate tapes covering each twelve-month survey period will be available for sale by the end of 1976. Expenditure components and detail on the tapes will be limited to that which will be published in the combined year reports.

Limited data from the quarterly interview component of the survey have appeared in two reports thus far (U.S. Dep. Labor 1976a, b). Information on vehicle purchase and repair expenses by selected family characteristics for 1972 and 1973 were published in November 1975 (U.S. Dep. Labor 1976a).

Additional selected data on food, tobacco, utilities, house furnishings and equipment, clothing, transportation, reading, education, and gifts and contributions classified by selected family characteristics were published for 1972 and 1973. Expenditures are presented as weighted averages of all sample families represented by the table column characteristics, regardless of whether or not each family reported a particular expense. The mean expenditures of those families actually making purchases can be derived by dividing the weighted sample mean by the percentage of families reporting the purchase. For example, BLS Report 455-1 indicates that U.S. families spent on the average $323.70 on the purchase of new domestically produced automobiles in 1972 (U.S. Dep. Labor 1976a). However, only 9.16% of U.S. families made such purchases. They spent on the average $3,534. Work is continuing to supplement this report with tabulations to appear soon, which will include expenditure data on the above components plus housing, home repairs and maintenance, household operations, alcoholic beverages, health care, selected personal care expenses, recreation, and insurance. Thus, all the components covered by the interview survey will be available soon, but not all the detail for each component. These reports contain what is called summary tables and will cover the periods 1972 and 1973. More detailed tables are planned for next year.

Microdata public-use tapes similar to those for the diary but containing the summary information from the interview component are planned for release in early 1977. These tapes combine selected characteristics with all expenditures reported in the interview survey aggregated to the items shown in the tables.

To recapitulate, neither the diary nor the interview covers the total range of consumption expenditures. The interview covers 90% of them, including global data on food purchases, alcoholic beverages, and tobacco. Three expense components—housekeeping supplies, personal care products, and nonprescription drugs—are not asked at all. A few other expense components in the interview have small pieces missing; for instance, the telephone component contains no data for coin telephone calls.

Problems in Integrating Survey Components

In order to provide a complete account of all expenditures, it is necessary to integrate data

from the two survey components. The Bureau of Labor Statistics plans to do this in publications of data to become available early next year but does not plan to integrate at the microlevel because of the lack of a generally acceptable methodology to accomplish this. Thus, there will be no integrated tapes. Users will have to make their own decisions about data matching and merging techniques. Therefore, it is important to call attention to the types of problems that have to be addressed before undertaking integration.

Plans originally called for the diary to be initiated concurrently with the interview survey. However, because of the lateness in receiving results of diary pretests and the initial burden of interview survey data collection on the Census Bureau's interviewing staff, the diary was not fielded until late June 1972.

The major problem for integration is this difference in the time period coverage between the two survey components, the interview covering annual expenditures for the periods 1972 and 1973 and the diary providing weekly expenditure data for the twenty-four-month period, July 1972 through June 1974.

There is one time period that holds potential for integration—calendar year 1973. Appropriate weeks from each year of the diary can be converted to estimates for 1973. While the collection periods for the two components overlap for the eighteen-month span, July 1972 through December 1973, because of the variable length recall periods in the interview survey, integration over this period is not possible.

Those wishing to integrate on a 1973 basis must address and solve a number of conceptual problems. Income estimates from the second-year interview survey refer specifically to the calendar year 1973 period, but this is not the case with respect to the diary. Diary panel families sampled in calendar year 1973 reported their income for the twelve-month period prior to the week paneled. For example, a diary respondent paneled in January 1973 provided an income estimate for the period January 1972 to January 1973. Thus, while the expenditures reported in the diary can be related to the twelve-month calendar period 1973, the income estimates for those families theoretically reflect an approximate midpoint period of December 1972 to January 1973.

Another integration problem is accounting for the difference in the income level between the two survey components. We have already noted differences with regard to the completeness of reports as collected. In addition, because the quarterly interview questionnaire collected income in great detail, these data may generate higher family income estimates than those from the diary.

Finally, users should be aware that tapes of quarterly interview data will contain estimates of both family income before taxes and income after taxes, while the diary tapes will contain only the former. Estimates for personal income taxes were not collected in the diary.

One difference in the concept of expenditures on the tapes of the diary and interview surveys is in the treatment of gifts. Purchases of items given as gifts to persons outside the family are normally excluded from current consumption estimates. Expenditure data on the interview survey tape do not include such purchases, which are identified separately in a summary classification. However, they are not so separated on the diary tape. This difference is trivial since the incidence of gift purchases for the expenditure classes on the diary tape is known to be small.

An important issue in determining the form and detail level of data for the tapes is that of confidentiality. Appropriate controls on the level of characteristics and expenditure detail in the published tables ensure that no family or individual respondent can be identified.

No such controls can be put on the uses to which data from public use tapes will be applied. BLS, in complying with its own standards as well as those of the Bureau of the Census, has chosen to handle the problem by limiting the level of detail on the tapes. This has been done in three specific ways.

First, the expenditure data and the item detail of expenditures were carefully inspected for unusual entries. The item classification levels were defined such that a maximum of expenditure detail could be provided but above a level permitting identity of the respondent.

Second, family and family member incomes were carefully screened. Reports less than $2,000 and those exceeding $35,000 were presented as coded variables rather than as direct observations.

Third, the geographic information available at the microlevel was limited to include only a region code, a code identifying three size classes of standard metropolitan statistical areas, each further broken down by inside and outside central city, and one code for non-standard metropolitan statistical areas further defined by a urban-rural breakdown. No individual areas will be identified for the time being.

Tapes for both survey components contain a set of important characteristics about the family and family members. The tapes of diary data include references to week of collection, so that users may assess the frequency and dollar volume of purchases on individual items over time. The interview tapes will contain pointed characteristics on housing and housing services such as number of rooms and type of utilities used.

BLS has learned a great deal about the collection, processing, and dissemination of consumer expenditure and income data from the conduct of this survey. It would be unfortunate if another twelve years were to elapse before the survey could be conducted again, particularly in view of the need for current expenditure information. BLS has proposed to conduct a survey of this type on a recurring basis. The merits of such a program are obvious. Limited planning funds have been provided by the Congress, and the planning activities are already under way. Final, larger funding has not yet been approved. It is hoped that the administration and the Congress will provide this project with the priority it deserves.

Discussion

Ronald A. Schrimper

The three papers in this session reflect a sense of new interest in the general area of demand and consumption analysis. Some of the same resurgence of interest with respect to demand and consumption analysis of agricultural commodities undoubtedly is related to increased interest in the type of forecasting and policy analysis described by Manchester. Recent demand-supply-price interactions in the agricultural sector may be partly responsible for renewed interest in these issues.

New types of empirical research using extensively detailed micro sets of data have been facilitated by improved computational capabilities in recent years. New capital stocks of data are always enticing to empirically oriented researchers. An important question is how new stocks of data can be used most efficiently to increase knowledge about demand and expenditure behavior. In view of existing computer capabilities, it is especially appropriate to review alternative proposals for additional exploitation of cross-section data. Many researchers are probably anticipating the availability of new national cross-section data sets for the United States provided by the 1972–73 Bureau of Labor Statistics (BLS) expenditure survey and the planned 1977 U.S. Department of Agriculture household food consumption survey.

If I correctly perceive the characteristics of the new BLS data from the highlights presented in Baer's paper and other sources, it presumably should be more detailed in the time domain but less comprehensive with respect to individual household expenditure profiles than previous studies. Data from the quarterly interview segment will be quite global with respect to expenditure categories (although not 100% coverage as noted by Baer) but will provide insufficient detail on food expenditures for many types of questions of interest to agricultural economists. On the other hand, more detailed information on food and a few additional subgroups of purchases will be provided by the diary component. Combining summary statistics from the two segments may provide accurate estimates of average expenditures for various subgroupings of households, but complete profiles of micro expenditure allocations for individual households will not be available. This shortcoming is extremely unfortunate. Nevertheless, governmental interests in data collection are not always compatible with ideal information systems for other types of basic and applied economic research. The resulting individual household BLS data sets will be useful for questions requiring aggregate expenditure categories or in cases where strong separability conditions are assumed to exist between food and nonfood expenditures. Some of the decisions about suppressing information already collected because of confidentiality and other guidelines will further restrict the data's usefulness to researchers. Justification of increasing funding for more frequent replication of activities of this type may require that more attention be directed to the information's potential for research purposes.

The methodological emphasis of the first paper is on the introduction of household characteristics into systems of relationships consistent with the interrelatedness of behavior resulting from household budget constraints. Attention is also directed to results of estimating separate models for subgroups of the population classified by selected household characteristics. Manchester advocates trying to understand behavior of different subgroups in the population as a way of improving knowledge about aggregate demand behavior.

Attempting to analyze cross-section consumer data within a consistent framework incorporating the interrelatedness of behavior imposed by household budget constraints is very appealing and increasing in popularity. The success of exploratory efforts in this

Ronald A. Schrimper is a professor of economics, North Carolina State University.

area is encouraging. Currently, this approach is not without its problems, because of certain restrictions and limitations as indicated by several caveats cited by Howe. Newer theories of household production and consumption also imply additional behavioral constraints over and above the budget constraint on market purchases. Some areas for additional work seem fairly evident before this approach is likely to address effectively the type of policy-oriented issues noted by Manchester. One of the most serious limitations of adapting linear expenditure systems for cross-section applications seems to be the implied linearity of Engel curves. Some suggestions regarding how this restriction might be relaxed are mentioned by Howe, but unfortunately this issue was not pursued in any of the empirical studies reviewed. The studies based on data from Mexico and Yugoslavia provided some indirect but conflicting empirical evidence on this point. Of course, income could be used as one of the criteria for subgrouping, assuming constant marginal budget shares within each group. An alternative way of handling this problem in a limited way is a spliced constant elasticity of substitution (CES) expenditure system proposed by McElroy. A description of the latter system, using McElroy's words is, "specifically, each Engel function consists of two abutting linear segments and thus marginal budget shares may differ between low and high levels of income" (p. 765). Other parameters in the spliced CES expenditure system are assumed to depend on sociodemographic characteristics of the household in much the same way as cross-section attributes have been introduced in adaptations of the linear expenditure system.

The manner in which sociodemographic characteristics of households are generally introduced into expenditure systems illustrates one of the theoretical shortcomings for understanding consumer behavior noted by Manchester. The problem exists since most cross-section empirical applications are within the context of household behavior, but theoretical structures are solidly rooted in terms of individual behavior. For example, the linear and spliced CES expenditure systems can be explicitly derived assuming an individual maximizes "reasonable" utility functions. The utility functions provide no information, however, concerning what characteristics of the household are expected to affect parameters of the model. For example, in practical terms, it is not obvious how age and sex composition differences among households should be represented. What are the guidelines concerning how many variables, what age groupings, etc., that should be used? Consequently, it is easily understood why many different characteristics are used for translating models in different ways or are used for subclassification of a sample. If theory is not capable of guiding empirical procedures, a wealth of new data can be overwhelming. Howe's admonition about the need for careful judgment to prevent criteria for subclassification proliferating so rapidly as to become unwieldy is especially important. Extensive subclassification can produce empty cells or some with too little data for estimation purposes.

Manchester's case for disaggregated models is based on interest in distributional effects of economic developments and policy changes in addition to his arguing that this will lead to improved estimation of aggregate effects. With regard to the latter point it is important to remember Grunfeld and Griliches's conclusion that disaggregated models may lead to inferior results because of specification errors associated with subcomponents. Consequently, if an ultimate goal is prediction of aggregate behavior, one may be better off with aggregate models. The following words of Grunfeld and Griliches seem especially cogent on these points: "It is undoubtedly true that disaggregation has certain advantages. In particular, it may suggest to us how to improve our theory. It may be futile, however, to expect that disaggregation will result in a better explanation of the aggregates without an appropriate change in the model. Different levels of aggregation require theories with different levels of abstraction" (p. 10).

There is no question in my mind about certain shortcomings in the current theory of demand, but I do not concur totally with some of Manchester's assessment. In particular, his comments about equilibrium and disequilibrium are troublesome. Casual empiricism suggests consumers are always adjusting to a variety of dynamic elements in our economy. Changes in consumer purchasing power, modified price relationships, introduction of new products, increasing educational levels, alterations in size and composition of households, and shifting occupa-

tional and geographical patterns of the population are among factors recognized as altering demand behavior. These can produce changes in consumption patterns, but is this change a symptom of disequilibrium or part of the dynamic process of adjusting to new equilibria? More information is needed about the adjustment process. Without this type of information, what basis is there for excluding households from analysis on the basis of disequilibrium and simultaneously concentrating on others assuming they are in equilibrium? Part of my concern is probably only a matter of semantics, but I am bothered by what criteria to employ for differentiating a household in disequilibrium from one in equilibrium.

Finally, I do not believe the concepts of optimization and maximization are ready to be discarded as useful elements in the theory of consumer behavior considering their fundamental role in all aspects of economic theory, especially in this bicentennial year of the *Wealth of Nations*.

Sources and Effects of Instability in U.S. Agriculture: Some Recent Experiences
(Jimmye S. Hillman, University of Arizona, Chairman)

Sources of Commodity Market Instability in U.S. Agriculture

Robert S. Firch

Cash receipts from U.S. farm marketings rose by 42% from 1972 to 1973, the largest year-to-year increase in sixty years. However, the 1916–17 and 1941–42 increases were only slightly smaller. Research completed in the early 1960s suggested that the importance of the farm income instability problem was at that time of small and declining importance (Firch 1964). The volatility of farm income that has occurred in the last ten years suggests a need to reevaluate the extent and sources of this instability.

Most of the literature on the sources of farm income instability has viewed the general business cycle and variations in farm output as the dominant sources of the instability (Schultz, Johnson, Cochrane, Hathaway, Firch 1964). During the last ten years the U.S. economy experienced a surge of inflation that was greater than in any comparable period since 1941–50. Recent research on the effects of general inflation during 1913–74 has revealed that the farm value, as measured by the U.S. Department of Agriculture market basket statistics, increased 1.77% for each 1% increase in the gross national product (GNP) implicit price deflator (Firch 1975), suggesting that inflation may have been an important source of farm income instability during the last ten years.

Analytical Procedures

The basic procedures used to develop the results that are presented in the following two sections are essentially those outlined in a previous article by Firch (1964). These procedures involve the application of regression analysis and the manipulation of regression coefficients with variances and covariances of the explanatory variables to allocate the variance of the explained variable to the variance of each of the explanatory variables and the covariance of each pair of the latter variables. In order to simplify the presentation and interpretation, each of the covariance terms has been allocated to the variance terms in proportion to the square roots of the variance terms.

All data series that are measured in dollar terms have been deflated by the GNP implicit price deflator on the belief that relative rather than absolute dollar changes represent the relevant variance to be studied. The computations of variances, covariances, and regression coefficients are performed on the first differences of the natural logs of the data series. The resulting first differences are good approximations of the percentage changes that would be computed by using the midpoint of the change as the base for the percentage calculation. First differences cause the variances and covariances to be based upon deviations from the trends in the data series. Hence, if a data series increases by the same percentage each year, it would have a zero variance. The economic interpretation is that market participants can readily adjust to increases of the same percentage each year, but a serious economic problem occurs when an important variable has highly variable year-to-year percentage changes and thus becomes unpredictable.

Robert S. Firch is a professor of agricultural economics at the University of Arizona.
Arizona Agricultural Experiment Station Journal Article 2650.

Analysis of Sources of Gross Farm Income Instability

The initial focus of the analysis is to discover the amount of variance of cash receipts of farm marketings, hereafter referred to as market receipts, that is correlated with the variances of the proposed explanatory variables of national income as a proxy for the general business cycle, the index of farm output, and the GNP implicit price deflator representing inflation.

Table 1 shows that the variance of market receipts in 1966–75 was much higher than it was in either of the two preceding ten-year periods, and the variance was nearly as high as during 1920–29. Farm output in 1966–75 had a greater variance than in the other two post-World War II periods but far below the variance of 1930–39. The variance of inflation appears to have trended downward from earlier to later periods. The low variance of inflation for 1966–75 may seem unrealistic, but the variance is based upon deviations from trend. The average year-to-year increase in the GNP implicit price deflator in 1966–75 was 6.2%.

Table 2 reports the variance of market receipts that correlated with the explanatory variables in selected time periods. Nearly 60% of the relatively high variance of market receipts in 1966–75 was correlated with the variance of the business cycle. Of the periods analyzed, only 1930–39 suggests a comparable dominance of the business cycle as a cause of variance in market receipts. Farm output shows only a relatively small contribution to the variance of market receipts in 1966–75 and seems to be the most important source of instability only in 1956–65 and 1920–29. Changes in inflation seem to have been an important source of market receipts instability for 1920–29, 1930–39, and 1946–55 but not in the two more recent periods.

Table 1. Variances of Market Receipts and Explanatory Variables for Various Time Periods

Time Periods	Market Receipts	Business Cycle	Farm Output	Inflation
		$(\%\Delta)^2$		
1966–75	134	11	22	4
1956–65	20	7	9	[a]
1946–55	28	20	16	16
1930–39	225	171	173	32
1920–29	138	34	35	39

[a] The value is less than 0.5.

Table 2. Variance of Market Receipts That Correlates with Explanatory Variables for Various Time Periods

Time Periods	Explanatory Variables: Business Cycle	Farm Output	Inflation
		$(\%\Delta)^2$	
1966–75	79	8	6
1956–65	1	12	2
1946–55	4	4	16
1930–39	127	14	35
1920–29	20	44	34

Since the 1974–75 recession was the most severe recession since the 1930s, it is perhaps not surprising that the business cycle should cause as much variance in market receipts in 1966–75 as the data of table 2 suggest. But the variance of market receipts attributed to the business cycle in 1966–75 as related to the size of the variance of the business cycle seems entirely out of proportion with this relationship for the four earlier time periods. Similar analyses completed in the early 1960s showed that the automatic stabilizers in the economy had become progressively more effective in stabilizing disposable income relative to national income over 1913–62 (Firch 1964). The automatic stabilizers include corporate income tax, corporate saving, personal income tax, net government transfer payments, the unemployment insurance program, and other welfare programs. Although the variance of year-to-year per capita dollar changes in national income was slightly more than half as large in 1966–75 as in 1930–39, the variance of disposable income in 1966–75 is less than one-fourth its value for 1930–39. It seems incomprehensible that the U.S. business cycle could have caused as much variance in market receipts in 1966–75 as the data of table 2 suggest.

A more satisfactory explanation of the 1966–75 farm income instability would likely result from adding a variable representing foreign demand for U.S. agricultural commodities. Foreign demand would logically be affected by the business cycles of major foreign purchasers of U.S. commodities, but the business cycles of other major economies seem to have become more closely correlated with the U.S. business cycle in recent years.

The U.S. business cycle variable in the current analysis probably tends to function as a proxy for foreign demand, and there is no feasible way to partition the two explanatory variables. The severe decline in the Peruvian fishing industry and the decision of the U.S.S.R. to purchase large quantities of grains in western markets to compensate for shortfalls in its own production also likely caused shifts in the foreign demand during the last ten years that had a high correlation with the U.S. business cycle. Another likely source of instability in recent years is the major instability in the exchange rate of the dollar against other major world currencies. The importance of this variable for U.S. agriculture was well documented by Schuh.

Attempting to identify the effects of exchange rate instability would likely yield more substantial results than attempting to isolate the total instability arising from foreign demand per se. Unfortunately, there exists no single variable that universally represents the exchange rate. The exchange rate of the dollar against the German mark was chosen to represent the exchange rate against all foreign currencies because Germany has a substantial trade with the United States, and it has one of the more stable economies.

Table 3 presents the results obtained from inserting the foreign exchange rate into the analysis for 1966–75. The exchange rate appears to be the most important source of variance in market receipts. A substantial part of the market receipt instability is still correlated with the business cycle, but as argued previously a substantial part of this probably has its source in foreign demand rather than the U.S. business cycle. The instability attributed to farm output rises slightly from the previous analysis, while the instability correlated with changes in inflation drops to an insignificant level. The earlier research indicated that farm prices were allowed to move freely during the 1971–73 period of price controls while the farm-retail spread and retail food price, as measured, were substantially constrained or delayed in their movement (Firch 1975). The price control program probably eliminated what otherwise might have been substantial correlation between market receipts and the GNP implicit price deflator during 1966–75.

Table 3. Variance of Market Receipts That Correlates with Explanatory Variables, 1966–75

Time Period	Explanatory Variables			
	Business Cycle	Farm Output	Inflation	Rate of Foreign Exchange
	(%Δ)²			
1966–75	48	9	[a]	69

[a] The value is less than 0.5.

The data of tables 1 and 3, when placed in perspective with Schuh's discussion of the exchange rate and U.S. agriculture, strongly suggest that government policies resulting in high commodity price supports and an overvalued dollar during 1946–55 and 1956–65 effectively buffered the variance of market receipts from the instability of foreign demand and largely explain the relatively low variance of market receipts in these periods. Historical perspective may eventually show that the high market receipts instability associated with the foreign exchange rate was unique to the 1966–75 period as the adjustment was made during 1971–73 from a system of fixed exchange rates and a substantially overvalued dollar to a system of primarily flexible exchange rates and a dollar essentially valued under free-market conditions.

Analysis of Sources of Income Instability for Cotton, Wheat, Corn, and Soybeans

Cotton, wheat, corn, and soybeans were selected for individual study because each represents a substantial portion of both cash receipts from farm marketings and exports of U.S. agricultural commodities. In recent years the four commodities have totaled about one-third of farm income and 60% of the export value of agricultural commodities. Direct government payments have been included as a part of the commodity income in these analyses because in some years during 1966–75 these payments became substantial portions of gross receipts for these commodities. To ignore the payments would in a sense overstate the variance of income. The same time periods were used, except that the data for corn and soybeans were unavailable in published sources for some of the earlier periods.

The analyses on the individual commodi-

ties were organized with a major objective of isolating the effects of inventory changes (as measured by changes in the quantity of carryover from the beginning to end of each marketing year) on the instability of income. This special interest in studying the effects of stock changes is based upon the belief that under certain circumstances such changes could substantially buffer the income instability from the other variables in the system.

The analytical procedure used was to include inventory changes as one of the variables in the least-squares regressions. The covariance terms and the variance term of the stock change variable were allocated to the other variables in a manner paralleling the analysis of the preceding section. The negative values in table 4 indicate that the nature of the covariance terms of that variable in that time period was such that it not only made no net contribution to the variance of income but also offset additional income instability from other variables.

Table 4 presents the variances of the individual commodity incomes for various time periods, and portions of this variance are attributed to the business cycle, changes in quantity produced, and exports. The export variable was represented by the rate of foreign exchange in 1966–75 and by quantity exported for other periods. The variances of commodity incomes are uniformly higher than the variance of market receipts for all commodities for the same time periods. However, the change in level of variance from one time period to another is proportionately less for the individual commodities than it is for total market receipts.

The table 4 data parallel the data in table 2 in suggesting that the general business cycle was the largest source of income instability during 1966–75. The business cycle is likely functioning as a proxy for certain shifters of foreign demand, even though the analysis includes a variable to represent foreign demand. The business cycle was apparently not an important source of commodity income instability for periods prior to 1966–75, except for wheat in 1930–39 and corn in 1946–55.

Cotton is the only commodity that shows quantity produced as an important source of income instability in 1966–75. In 1956–65 the largest portions of income variance were correlated with the production variable, and it is the most important source of income instability for cotton and wheat in 1946–55 and cotton and corn for 1930–39.

Table 4. Variance of Cotton, Wheat, Corn, and Soybean Income That Correlates with Explanatory Variables for Various Time Periods

Time Periods	Variance of Commodity Income	Explanatory Variables: Business Cycle	Quantity Produced	Exchange Rate or Exports[a]
	(%Δ)²			
	Cotton			
1966–75	432	241	61	101
1956–65	203	1	191	−1
1946–55	231	5	228	−2
1930–39	667	13	339	25
1920–29	749	−7	197	455
	Wheat			
1966–75	544	65	19	427
1956–65	230	4	194	2
1946–55	397	4	334	12
1930–39	789	266	101	96
1920–29	508	19	35	174
	Corn			
1966–75	349	322	−26	50
1956–65	110	11	25	29
1946–55	180	121	−3	33
1930–39	523	−3	75	22
	Soybeans			
1966–75	523	282	4	201
1956–65	121	1	74	38
1946–55	278	2	74	101

[a] The rate of foreign exchange was used for 1966–75, and the quantity exported was used for other periods.

Variations in export demand appear to have been important contributors to income variance for all four commodities in 1966–75. The export variable had the largest portion of income variance correlated with it for corn in 1956–65, for soybeans in 1946–55, and for wheat and cotton in 1920–29.

Table 5 reports the imputed stabilization by stock changes that otherwise would have been correlated with individual commodity income for each of the variables. This shows that, with the exception of wheat and soybeans in 1966–75 and cotton in 1956–65, inventory changes buffered variance that would otherwise have arisen from changes in production for each of the four commodities and for each of the time periods beginning after 1945. Stock changes were apparently very important stabilizers against production

Table 5. Stabilization of Cotton, Wheat, Corn, and Soybean Income by Stock Changes[a]

Time Periods	Business Cycle	Quantity Produced	Exchange Rate or Exports[b]	Total Stabilization (% of Income Variance)
	---------- (%Δ)² ----------			
	Cotton			
1966–75	−18	75	−7	11.76
1956–65	21	−28	1	−3.45
1946–55	−4	136	4	58.57
1930–39	8	244	3	38.25
1920–29	31	282	−157	20.79
	Wheat			
1966–75	38	−11	113	25.70
1956–65	4	16	[c]	8.47
1946–55	57	140	−11	46.97
1930–39	−94	−124	90	−16.25
1920–29	10	−2	−41	−6.52
	Corn			
1966–75	−174	207	−43	−3.03
1956–65	−7	12	−11	−5.64
1946–55	−32	38	−27	−11.53
1930–39	6	−76	72	0.31
	Soybeans			
1966–75	40	−4	17	10.02
1956–65	−2	18	8	19.02
1946–55	−1	41	−6	12.19

[a] Negative signs indicate destabilization.
[b] The rate of foreign exchange was used for 1966–75, and the quantity exported was used for other periods.
[c] The value is less than 0.5.

variations for cotton for 1930–39 and 1920–29. Stock changes seem to have amplified the income variance correlated with production variance for wheat and corn for 1930–39.

Stock changes appear to have been destabilizing in relation to the business cycle as a source of income instability for cotton and corn for 1966–75. Buffering of income instability against the business cycle seems to have been important for wheat and soybeans in 1966–75, for cotton in 1956–65 and 1920–29, and for wheat in 1946–55.

The inventory change variable was correlated with exports so as to reduce income variance for wheat and soybeans for 1966–75 and wheat and corn for 1930–39. For all other combinations of commodity and time period, stock changes amplified or had inconsequential effects for export quantity on income variance.

The data of table 5 indicate that inventory changes have generally been very effective in stabilizing income relative to changes in production. The only major exceptions to the tendency of stock changes to be more beneficially responsive to production changes than the other two variables were wheat and soybeans in 1966–75, cotton in 1956–65, and wheat and corn in 1930–39. This may be explained by the availability of better data on expected production than on the effects of the business cycle or export demand. In this way free-market participants can and do respond more effectively to the production variable than to the other variables.

The final column of table 5 shows the total stock change stabilization computed by summing the values of the three variables and dividing this by the variance of income that actually occurred. This shows that in 1966–75 stock changes were stabilizing for all but corn. Stock changes were destabilizing of income for cotton for 1956–65. The Commodity Credit Corporation accumulated huge quantities of cotton during 1956–65 and carried its largest accumulation into the beginning of 1966–75. The inability of stock changes to stabilize income seems strongly related to the freedom of free-market participants to influence stock changes, which is supported by the substantial stabilization for soybeans for each of the three periods studied. The Commodity Credit Corporation has had only very limited ownership of soybean stocks with its largest involvement coming in 1966–75. The corn income destabilization by the stock change variable may reflect its functioning within a very complex feed-livestock system rather than in the simple model specified in this analysis.

These studies strongly support the idea that the free-market stock change variable may truly be the forgotten variable in understanding the problem of farm income instability. Any commodity reserve program that is intended to stabilize farm income will likely neutralize a substantial amount of free-market stabilizing capacity before it achieves any net stabilization of income.

Instability in the Capital Markets of U.S. Agriculture

C. B. Baker

Instability in capital markets of U.S. agriculture can be reflected in interest rates paid and charged by agricultural lenders, in loan volumes, total and by lender, and in loan quality of lender portfolios. In this paper I focus principally on interest rates and market shares. Both reveal important aspects of economic performance by participants in agriculture capital markets, as well as sources and forms of instability. My concern is limited largely to debt capital markets because they supply the vast bulk of market-supplied capital in U.S. agriculture.

Agricultural Capital Markets

Like all markets, capital markets evolve in response to opportunities for specialization and exchange among market participants. Exchange in capital markets is made possible through the use of negotiable debt instruments: money substitutes with time dimensions. Individuals, firms, and agencies differ in the values they place on debt instruments relative to money. These differences make financial markets possible and give rise to "financial intermediation," a process that transforms debt instruments in terms of liquidity, maturity, and/or security.

Informal Markets

As in the rest of the world, U.S. agriculture is financed through informal as well as formal capital markets, the informal ones consisting of individuals and trade lenders. Individuals include those who lend within the family, especially in helping the young start farming, and those who finance the sale of farm supplies or farm capital, including land as well as depreciable assets. Individuals account for more than 33% of loans secured by real estate (Melichar et al.). Sellers can use land purchase contracts to reduce tax liabilities on capital gains. In addition many retired farmers regard land purchase contracts as desirable investments. Terms of land purchase contracts are negotiated along with the price of land, limiting the significance of reported values of both. Thus, individuals remain strong competitors in the supply of debt capital to agriculture, as they function with a minimum of financial intermediation.

Individuals and others provide nearly 20% of non-real estate loans to farmers (USDA 1975). Trade credit is important in this category. Much of it is associated with machinery and equipment. Financing terms are often related to prices negotiated for the financed asset, making it difficult to interpret actual interest paid. Trade credit is also used to finance annual inputs: feed, fertilizer, fuel, etc. Annual inputs often are financed on open account for short periods as a matter of transaction convenience, perhaps with no interest paid (at least explicitly). In the case of both depreciable assets and annual inputs, credit is closely associated with merchandising practices of the trade firm, loans viewed in part as a method of expanding demand. Debt instruments in trade finance may and often do generate opportunities for financial intermediation and, therefore, financial markets.

Formal Markets

Formal agricultural capital markets consist of financial intermediaries who loan directly to farmers. Financial intermediaries can be sorted into the categories indicated in table 1.

C. B. Baker is a professor in the Department of Agricultural Economics, University of Illinois.

The author is indebted to T. L. Frey, G. D. Irwin, D. A. Lins, and E. L. Melichar for the helpful comments on an earlier draft of this paper. Thanks also are due to the Farm Credit Administration and Board of Governors of the Federal Reserve System for recent data used in the interest rate analysis.

Table 1. Farm-Related Financial Intermediaries Differentiated by Relation of Lender to Saver and Borrower

Relation to Saver	Relation to Borrowers in Agriculture	
	Specialized	Nonspecialized
Depository	None	Commercial banks
Nondepository	FCS units	Life insurance companies

The absence of a depository financial intermediary specialized in agricultural lending is interesting, especially in view of the success of savings and loan associations in urban mortgages and of savings units in agricultural sectors outside the United States.

Commercial banks provide a depository function for farmers as well as others. The banks then allocate funds made available by deposits among loan and investment alternatives, subject to organizational and legal constraints. Variability in the source of charter and in Federal Reserve membership varies the constraints under which banks allocate loanable funds. For example, in unit banking states a rural location can produce lending behavior that is heavily influenced by the dominance of farming and farm-related business activity.

The Farm Credit System (FCS) plays an especially interesting role in agricultural capital markets. In each of twelve districts the FCS units consist of a Federal Intermediate Credit Bank (FICB), a Federal Land Bank (FLB), and a Bank for Cooperative (BC). The FICB's buy debt instruments from local Production Credit Associations (PCA's), which make non-real estate loans directly to farmers. FICB's also discount a small volume of agricultural loans for commercial banks and other financial institutions. FLB's make farm-mortgage loans to farmers through local Federal Land Bank Associations (FLBA's). BC's loan directly to farm cooperatives. Debt instruments from farmers (and agricultural cooperatives) are sold by FCS units in national capital markets. The units are owned by the borrowers and are constrained by law to lend to agricultural participants and rural residents. Hence, they are specialized, functioning in a cooperative system with substantial control vested at the direct lending level.

The rate of interest paid by borrowers from FCS units is closely related to the interest rate paid to those who buy obligations of the units. Large city banks and life insurance companies are important buyers. The difference between interest paid and interest charged is for administrative costs of FCS units and for contingency reserves. Income also arises from investments made with proceeds from sale of capital stock to borrowers and with funds held in contingency reserves. The debt instruments are sold in national capital markets at interest rates only slightly higher than for obligations of the federal government that are comparable in maturity.

Life insurance companies comprise the remaining financial intermediaries who lend directly to farmers, largely in farm mortgage loans. Life insurance companies who participate do so cyclically and selectively. Being nonspecialized, they respond to profit perceptions as they allocate loanable funds among alternatives in loan and investments. The perceptions vary over the business cycle. Profits correlate positively with loan volume in relation to area. Hence, life insurance companies are active and competitive in areas of high land value and in periods when farm mortgage lending produces returns that compare favorably with alternative uses of company reserves.

Interest Rate Instability

Wholesale Capital Markets

Part A of table 2 provides for each lender the average interest rates paid for loanable funds, the annual average change for 1960–75 (column 1), 1960–67 (column 2), and 1968–75 (column 3), and the coefficient of variation from trend (CVT). Linear trend lines fitted to the data provide, with trend coefficients, estimates of the average annual changes. CVT's estimate variations from trend expressed in terms of means for the periods indicated. Differences in CVT's between the first and second halves of the period were tested for significance by comparing with the *F*-statistic the variance from trend, 1968–75, divided by the variance from trend, 1960–67. Computed ratios are shown in the fourth line for each lender. The probabilities of chance differences as large as those shown are less than 5%.

Table 2. Selected Statistics Relating to Interest Rates Paid and Received by Agricultural Lenders, 1960–75

[a] Calculated from annual time series (USDA, forthcoming).
[b] Weighted net cost to Farm Credit System banks of bonds outstanding at end of year.
[c] Calculated from annual time series: maximum interest rates payable on time and savings deposits (time weighted averages, all accounts and deposits) (Board of Governors).
[d] From series on contract rates on loans through FLBA. In computing the average rates, each Farm Credit district is given equal weights; within districts, rates are weighted by number of days in force.
[e] From series on rates that represent interest (minus patronage refunds), service fees, cost of record searches, and filing and releasing mortgages, etc., paid by borrower as percentage of average loans outstanding during year.
[f] From series on midpoints of ranges reported. Excludes rates on loans secured by CCC documents.
[g] Calculated from annual time series (USDA 1974).
[h] Coefficient of trend variable in trend equations fitted to date for the period indicated in the column head.
[i] Square root of mean of squared deviations from trend values, as a percentage of mean values for respective time periods:

$$\left\{\left[\frac{1}{n-2}\sum_t (i_t - \hat{i}_t)^2\right]^{\frac{1}{2}} + \frac{1}{n}\sum_t i_t\right\}(100).$$

The three FCS units differ little in mean interest rates paid to investors in their obligations. FLB's borrowed for slightly less than the other two units in 1968–75 and for slightly more in 1960–67. For FLB's the mean annual change was less in 1960–67 than in 1968–75. For all three units, the CVT was more in 1968–75 than in 1960–67. Among FCS units, FLB's were lowest in CVT in all periods. There was little difference between FICB's and BC's in given periods.

The last three rows of table 2, part A, show comparable statistics for commercial banks. Large certificates of deposit are excluded. The average rates paid in 1960–75 are considerably lower for commercial banks than for FCS units. The average annual increase also was less. The CVT nearly matched that of FLB's. In 1960–75, the annual increases resembled those of FICB's. One mild surprise: the CVT was significantly smaller in 1968–75 than in 1960–67. For banks, market instability was substantially greater in 1960–67 than in 1968–75, whether measured by trend or variance from trend. Since no interest can be paid for demand deposits, the averages reported are doubtless overstated. No attempt was made to weight the rates (paid by volumes deposited with banks in exchange) for the various instruments.

Retail Capital Markets

Part B of table 2 shows comparable statistics for interest rates paid by agricultural borrowers. For all three FCS units the annual increase was more in 1968–75 than in 1960–67. For FLB's the greater increase in the second half was consistent with the increased average annual changes in rates paid. For the

other two FCS units, the trend in 1968–75 compared with 1960–67 ran counter to average changes in interest rates paid. The variable interest rate policy adopted by FCS units doubtless influenced the mean annual change in 1968–75. The CVT was significantly higher for all three FCS units in 1968–75 than in 1960–67.

Average rates commercial banks charged farm borrowers are shown to be higher than those charged by FCS units. The slope of the trend line reveals that on the average the annual change in rates charged farmers was extremely small in 1960–67, despite a sharply increasing cost of funds. In 1968–75 banks and PCA's charged about the same average rates. Finally, we note a small increase in 1968–75 in the CVT for rates charged by commercial banks, small because it was low throughout the period. The direction of change was to be expected, but it ran counter to the direction of change in CVT for rates paid by commercial banks.

Shane has argued that an important function for financial intermediaries is to moderate variations in interest rates. Table 2 suggests a somewhat mixed pattern in agricultural capital markets. The upward trends in interest rates were less at retail than at wholesale for all agricultural lenders when 1960–75 is considered as a whole. The CVT also is lower for all but FLB's.

The interesting comparisons are those between 1960–67 and 1968–75. All three FCS units absorbed much of the trend increase in the cost of loanable funds during 1960–67, as did commercial banks. During 1968–75, all but FLB's increased interest charged by more than rates paid. Moreover, for all but FLB's the CVT also was higher for rates received than for rates paid. Perhaps the second half performance of agricultural lenders represents a delayed reaction to events of the first half. On the other hand, it may more accurately foreshadow the future than does either 1960–67 or 1968–75 as a whole.

Instability in Institutional Sources of Capital

Figure 1 (USDA 1975) shows the net annual amounts loaned since 1960. In this period net annual farm real estate loans increased nearly 400% (Melichar et al.). Net non-real estate loans increased by nearly 300%. Real estate debt outstanding has exceeded non-real estate debt since 1965, the result of a high rate of increase in average farm size (especially land) during the 1960s, rapidly increasing land prices especially since 1970, and perhaps some refinancing of non-real estate debt.

Figure 2 (USDA 1975) shows the shares of farm real estate debt held by principal farm real estate lenders. FLB's increased their share gradually during the 1960s, rather more substantially after 1967, and sharply since 1971. The Farm Credit Act of 1971 increased the loan maximum for farm mortgages from 65% of normal agricultural value to 85% of market value of farm land.

A contributing factor has been a decline in loan funds from life insurance companies. Before 1967, they held a market share exceeding that of FLB's. They have since diverted funds from farm real estate lending because of accelerating lending costs, increased demand for personal loans provided for in policy contracts, and higher earning options outside farm real estate lending. State usury laws and other lending restrictions also may reduce their ability to compete in farm mortgage lending. In any event, the declining share held by life insurance companies is an outstanding feature of the farm real estate loan market.

Meanwhile, the share held by commercial banks held nearly constant at about one-eighth of the total, while the share held by individuals has fluctuated narrowly within a range of 36% to 40%. Commercial banks have held their share of farm real estate debt at rates somewhat higher than are charged by the other principal farm real estate lenders. From the borrowers' point of view, the higher interest rates may be partly offset by lower transaction costs. Yet higher interest rates may explain the continued demand for farm mortgage debt instruments by commercial banks.

"Individuals and others" retain the highest share of real estate debt. For reasons already noted, individuals are strong competitors in farm real estate lending, and, barring changes in tax laws, they are likely to remain so. Rates charged borrowers appear to have remained remarkably stable over 1960–73 (Melichar et al.). Interest rates are but one feature of negotiations in land sale and finance between seller and buyer.

Figure 3 reveals changes in the share of

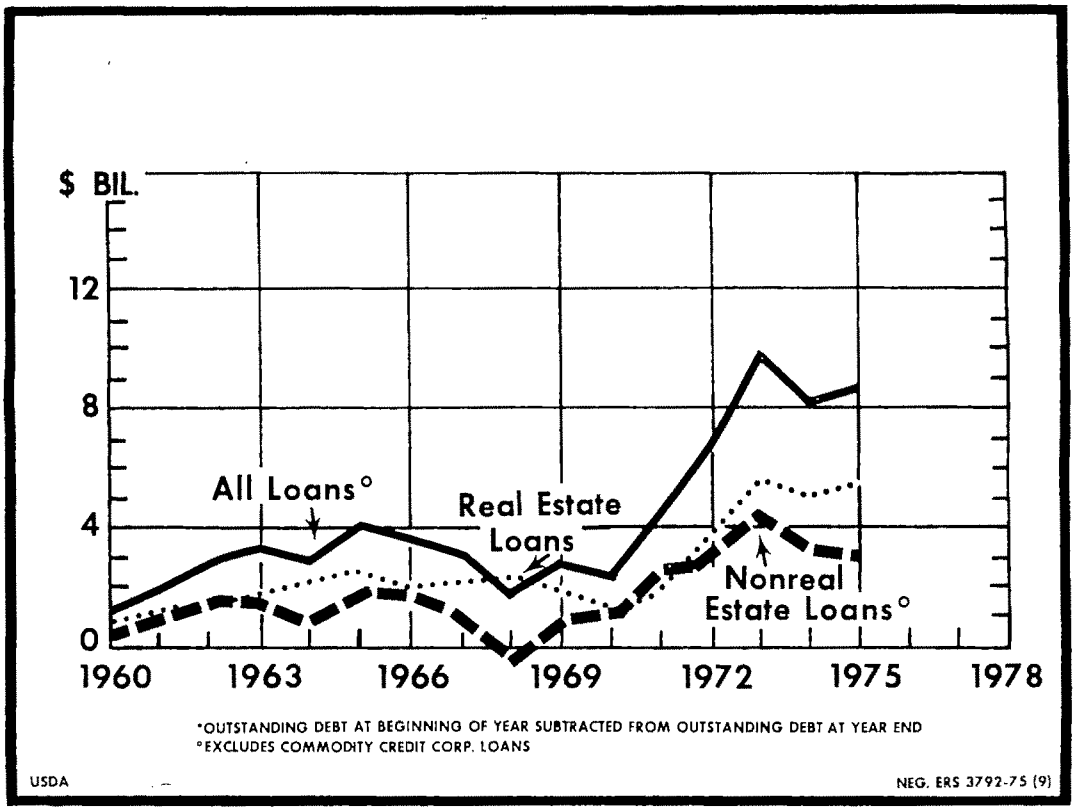

Figure 1. Annual net flow of farm loan funds

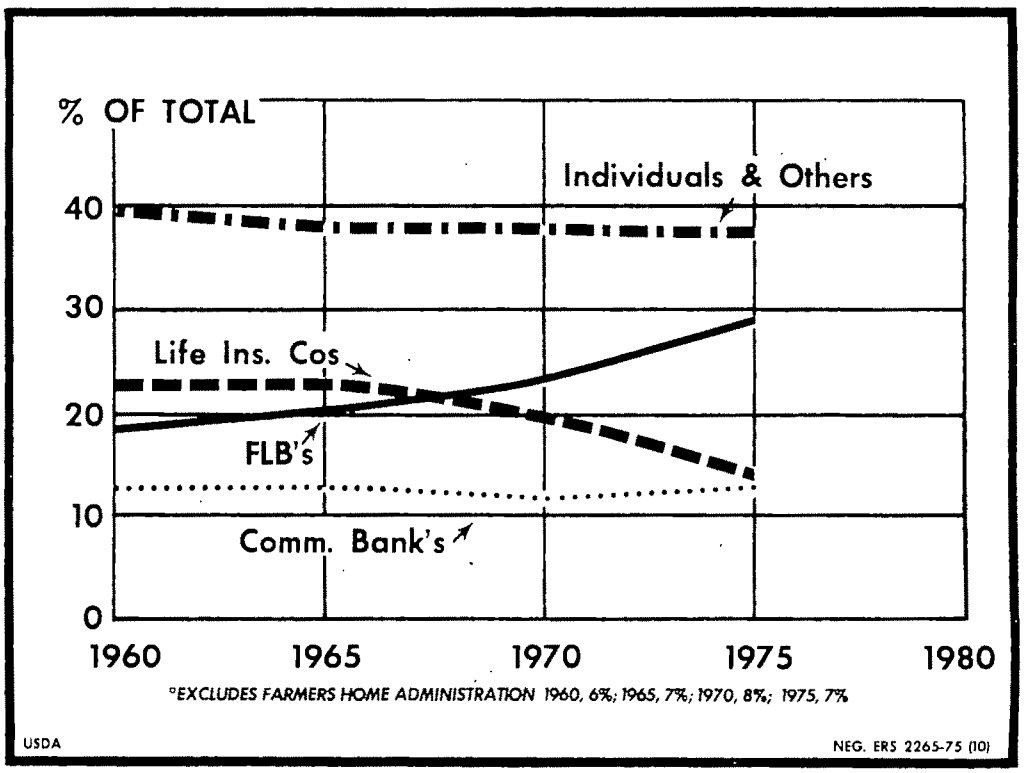

Figure 2. Farm real estate debt shares

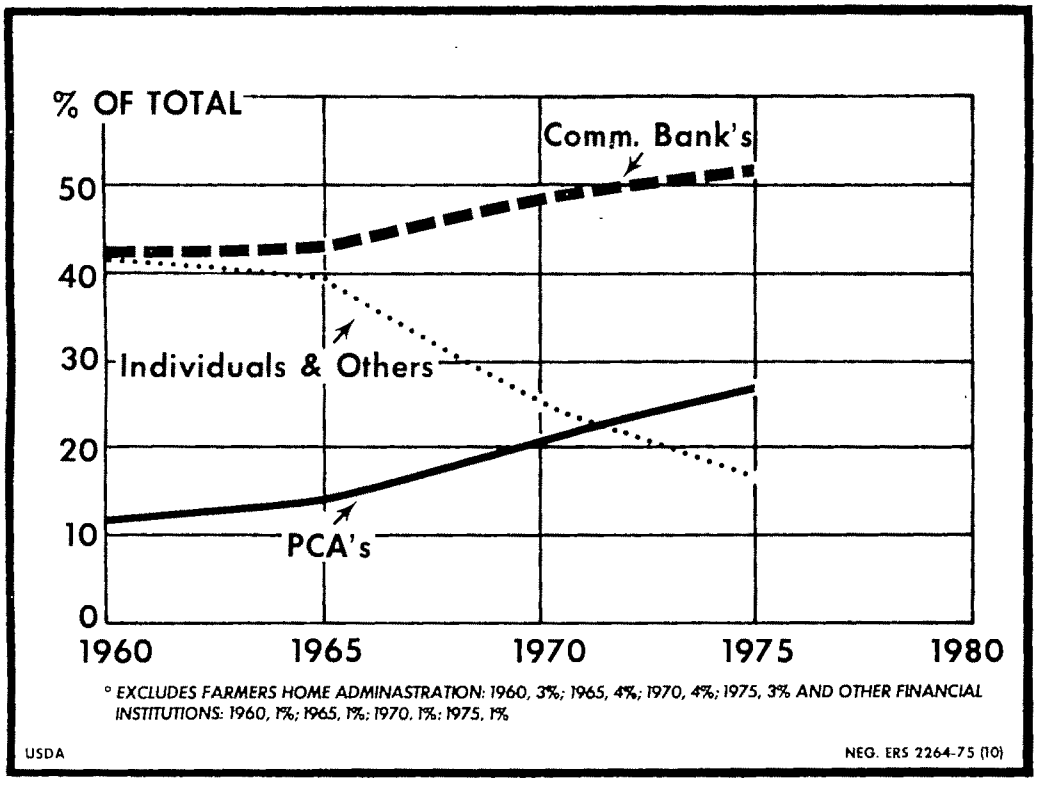

Figure 3. Nonreal estate debt shares

non-real estate farm debt among principal lenders. An important feature is the institutionalization of trade loans (reflected in "individuals and others") that has been occurring since 1965. Trade loans declined as a share of the loan market by thirteen percentage points between 1965 and 1970. Increases among PCA's and commercial banks in the years of sharpest decline in trade loans suggest that they may have shared about equally in the loans shifted from trade lenders. Otherwise, in contrast with life insurance companies versus FLB's, commercial banks have remained competitive with PCA's in the farm non-real estate capital market.

Finally, I note the share of farm non-real estate loans held by the Commodity Credit Corporation (CCC). CCC loans are nonrecourse loans to finance crop inventories. They reached nearly 13% of non-real estate debt in 1962. However, as a part of price support programs they constituted receipts from marketings in the 1960s. In any event, treasury-financed CCC loans have now dropped off sharply, being offset in part by commercial loans to farmers and other participants in the grain trade.

Banking Structure and Market Shares

Many rural banks are small, independent, and isolated from national financial markets. Hence, they are unknown to market participants and unable to generate financial transaction units of a size required in such markets (Sloan). Participants in national financial markets report that $200 million or more outstanding in a given type of paper is needed to support a good secondary market (Doll) and needed, in turn, to provide the liquidity required for marketing debt instruments. Outstanding debt farmers owe to commercial banks suggests that volume need not be an insurmountable problem, given that an adequate intermediary can be interposed between the rural banks and national capital markets.

Where the interposed intermediary is a branching headquarters of a bank, the question arises that a flow of funds may be activated from rural to urban users instead of the reverse (Melichar, Snider). Given the "entrapment" of funds in small local bank deposits (Baughman), a first consideration

suggests considerable economic merit in that effect. However, some dislocations also could be expected. Local equilibria now depend on rural deposits bearing relatively low rates of interest. Rates charged farmers did not (and do not) reflect these low rates. Indeed, in the early 1960s rates farmers paid commercial banks exceeded the urban prime rate and differed little from rates charged by PCA's.

Should a reorganized flow of funds add competitive pressures for local deposits in rural areas, farmers would face potentially higher rates of interest. In these circumstances, PCA interest rates might become effective "ceilings" on rates charged farmers by commercial banks. A study in Wisconsin suggests that branching need not convert the flow to net urban, though the results there may have been determined by the terms of branching permitted (Rosenblum).

There remains the question of economic effects of a net urban or net rural flow of funds. If net urban, then small banks in rural areas are transformed (partially) from retailers to wholesalers of loanable funds. Most buyers of FCS unit obligations are large city financial intermediaries, including money market commercial banks. Some of the balances now used for direct loans to farmers might instead flow to banks that buy FCS unit obligations. How much of the flow would be channeled to FCS units is a moot question. Sloan has suggested a marketing process designed to restrain a net urban flow of funds and possibly induce a net rural flow of funds.

Summary and Conclusions

The evidence suggests relatively little instability in agricultural capital markets in aggregate. The volume of funds borrowed by farmers has increased over the past several decades in both nominal and real terms. The increase in nominal terms exceeded inflation rates, as reflected in the value of assets in the farm sector especially before 1972. The increase in real terms reflects high expected payoff from use of borrowed funds in agriculture and lack of alternative means of financing added resources in agriculture. The farm sector remains essentially proprietorship (i.e., "full liability") organized.

Interest rates have varied at "wholesale" much like interest rates paid by financial intermediaries who raise funds for lending to other sectors. Interest rates have varied at "retail" perhaps a bit less than for other sectors. A contributing factor is the importance of small rural commercial banks in unit banking states (or states with limited branching). The imperfect markets tend, on balance, to restrain the flow of funds from rural to urban users. FCS units also have been able to absorb part of the variability of interest rates at wholesale, insulating farm borrowers from some of the extremes of the recent past, though the pattern is a bit mixed in recent years.

The past may not be a reliable basis for estimating the future behavior of agricultural capital markets. Further branching among commercial banks seems likely, on balance, to reduce the isolation of rural locations, producing interest rates that reflect more sensitively those paid elsewhere. Rapid growth of FCS units and the tendency in the past to absorb national variations in interest rates has exacted a price in terms of liquidity of FCS units. FCS units probably will be less able in the future than they were in the past to absorb variations in wholesale rates of interest.

Thus, future agricultural borrowers are likely to face capital markets that look increasingly like the capital markets of other borrowers. If the general increase in variability since the 1970 period is not dampened, then still another element of risk is increased for farmers. The changes also seem likely to reduce the supply or increase the cost of debt capital for a given equity base, adding to the demand for or supply price of equity capital in agriculture.

Asset Values and Liabilities of U.S. Farmers in Unstable Commodity and Capital Markets

David A. Lins

Previous papers by Firch and Baker identified sources of and changes in instability in commodity and capital markets. Changes in instability are likely to create modifications in the desired portfolio of farm operators, landlords, and other farm investors. The purpose of this paper is to review the instability of farm assets and liabilities held by U.S. farm proprietors.[1] The paper is divided into four main sections: first, the structure of assets and liabilities in the farm sector; second, farm asset and liability instability in comparison with the instability in commodity and capital markets; third, concepts of investment in a risky environment in relation to observed changes in the balance sheet for the farm sector; and fourth, existing econometric studies relating to farm assets and liabilities and the potential for including risk considerations in such studies.

Structure of Farm Assets and Liabilities

Farm real estate (land and buildings) is the major asset of farm proprietors (table 1). The value of land and buildings increased in nominal value from $130.6 billion as of 1 January 1960 to $422.3 billion as of 1 January 1976. However, only very modest increases in the real value of real estate have occurred. Real estate assets have accounted for an increasing percentage of total assets of farm proprietors on a nominal basis but for a relatively constant percentage on a real basis (table 2).

The nominal and real value of all non-real estate assets have also increased since 1960. In percentage terms, the largest increase in both nominal and real terms has been in farm machinery and motor vehicles. Also, the real value of crops stored on and off farms has held up well despite the withdrawal of most government support programs. Non-real estate assets as a percentage of total assets have trended downward on a nominal basis but have trended upward on a real basis. This pattern, coupled with the slight decline in the relative importance of the real value of real estate, suggests a trend toward more intensive farming practices.

Total financial assets of farm proprietors have increased in nominal value since 1960. However, farm proprietor investments in U.S. savings bonds have declined on a nominal basis. On a real basis, the holdings of demand deposits and currency has also declined since 1960. Investments in cooperatives have increased in both nominal and real terms. As a percentage of total assets, financial assets have declined since 1960.

Liabilities of farmers have increased tremendously since 1960. Total debt increased from $24.8 billion as of 1 January 1960 to $90.7 billion as of 1 January 1976. Real estate debt as a percentage of total liabilities has increased substantially, reflecting in part the increasing importance of real estate in the asset composition of U.S. agriculture. Trends in holdings of financial assets coupled with trends in debt outstanding suggest that farm financial assets are declining in importance as a source of liquidity for farm proprietors. This in and of itself does not imply a decline in the overall liquidity of farm proprietors.

David A. Lins is an agricultural economist with the National Economic Analysis Division, Economic Research Service, U. S. Department of Agriculture, and is an assistant professor in the Department of Agricultural Economics, University of Illinois.

The author wishes to thank C. B. Baker, J. B. Penson, and Lindon Robison for their constructive comments on an earlier draft of this manuscript.

[1] Farm assets and liabilities held by U.S. farm proprietors refer to those assets and liabilities recorded in the *Balance Sheet of the Farming Sector* (USDA). These figures are intended to record only farm assets, debts, and equities of farm operators and landlords; nonfarm assets are not included.

[a] Real values are obtained by dividing nominal values by the index of prices paid by farmers.

Instability of Farm Assets and Liabilities

There are a number of ways to measure instability. Two measures used here are the coefficient of variation (CV) and the coefficient of variation from trend (CVT).[2] These two measures of instability for balance sheet components are presented in table 3. Because of aggregation, these measures may not be an accurate indicator of instability experienced by individual farm operators. Calculations are done in both nominal and real terms for 1960–76. Since variations in nominal values of physical assets contain both quantity and price effects, CV's and CVT's for the own-price deflators for physical assets are also reported.

As shown in table 3, the CV as well as the CVT are substantially different from one balance sheet component to the next. For nominal balance sheet values, the three categories of financial assets display the three lowest CVT's, suggesting that on a nominal basis financial assets are the most stable asset in the balance sheet for the farm sector. Liabilities exhibit the next lowest CVT's, but the CV's are high relative to financial assets. Nominal values of physical assets appear to be the most unstable component of the balance sheet. In particular, the nominal value of crops stored on and off farms has a higher CVT than any other asset or liability.

Fluctuations in nominal values of assets can arise due to price or quantity changes. Fluctuations in physical units can be determined by reference to balance sheet values in real terms, while fluctuations in price can be measured by reference to the assets own-price deflator.

CVT's and CV's for balance sheet items in real terms are also presented in table 3. Results suggest that the physical stock of land and buildings used in U.S. agriculture is more stable than the physical stock of any other asset used in farming. Results also suggest that the real values of financial assets are no more stable than physical assets.

Are balance sheet values for farm proprietors more stable than commodity prices and financial markets?[3] Comparisons of annual

[2] Instability might also be measured as deviations between actual and expected outcomes. This measure requires knowledge of expectations of farm operators.

[3] Annual coefficients of variation and annual coefficients of variation from trend for prices received and paid are 30.3 and 22.8 for index of prices received on crops, 26.5 and 13.5 for index of prices received on livestock, and 26.3 and 12.7 for index of prices paid by farmers.

Table 2. Balance Sheet Components as a Percentage of Total Assets and Liabilities, 1960–76

Source; USDA.

CV's and CVT's for prices received and paid by farmers reveal that the stability of these items is about comparable to that for physical assets. Financial assets and liabilities appear to be more stable than prices received and paid by farmers. Interest rates on borrowed funds appear to be more stable than any of the physical assets or liabilities of farm proprietors (see CVT's reported by Baker). Financial assets appear to be slightly more stable than interest rates paid for borrowed funds.

Table 3. Measures of Instability in the Value of Balance Sheet Items for the U.S. Farm Sector, 1960–75

	Nominal Balance Sheet Values		Real Balance Sheet Values	
Balance Sheet Item	Annual Coefficient of Variation[a]	Annual Coefficient of Variation from Trend[b]	Annual Coefficient of Variation[a]	Annual Coefficient of Variation from Trend[b]
Physical assets[c]				
Land and buildings	39.9 (39.1)	17.3 (17.3)	1.1	0.3
Livestock and poultry	34.2 (27.6)	20.2 (18.3)	7.2	2.1
Machinery and motor vehicles	38.7 (31.2)	19.4 (16.3)	6.9	2.3
Crops stored on and off farms	40.8 (42.7)	23.7 (30.5)	9.9	9.1
Household equipment and furnishings	24.3 (18.5)	15.2 (11.9)	6.4	4.9
Financial assets				
Deposits and currency	20.4	5.0	7.6	7.3
U.S. savings bonds	8.1	7.4	25.6	2.2
Investment in cooperatives	30.8	8.1	8.9	6.4
Liabilities				
Real estate debt	44.8	10.7	22.7	7.2
Non-real estate debt including CCC loans	37.6	11.2	12.9	7.6

[a] The coefficient of variation is the standard deviation divided by the mean times 100.
[b] Each balance sheet item was regressed against time for 1960–75.
[c] Items in brackets are coefficients of variation and coefficients of variation from trend for the own-price deflators for physical assets. The deflator used for financial assets and liabilities (the index of prices paid by farmers) has an annual coefficient of variation of 26.3 and a coefficient of variation from trend of 12.7.

Investment in a Risky Environment

Determination of farm proprietors' responses to changes in their economic environment requires an understanding of their decision processes. Considerable progress toward such an understanding has been gained through the use of a decision theory concept of profit maximization. However, profit maximization as the sole criterion has come under increasing scrutiny and question. In particular, decisions involving risky choices may be poorly explained by a decision criterion based solely on maximization of profit.

In relation to investments in balance sheet components in a risky environment, a particularly useful conceptualization of the decision process appears to be expected utility theory and the closely associated theory of portfolio balancing. According to the latter theory, the decision to invest in an asset is not made independently of decisions regarding other assets and liabilities. This suggests a decision-making framework in which investment and financing decisions are considered simultaneously. (Ample evidence exists to suggest that in U.S. agriculture investment decisions are influenced by their impact on financial alternatives and vice versa.) The desired portfolio balance is that which maximizes expected utility.

Knowledge of risk aversion characteristics of investors provides useful insights to their decision processes. Working independently, Pratt and Arrow formulated two measures of risk aversion: absolute risk aversion and relative risk aversion. Decreasing (increasing) absolute risk aversion exists if the amount of wealth invested in risky assets increases (decreases) with wealth. Decreasing (increasing) relative risk aversion exists if the percentage of wealth invested in risky assets increases (decreases) with wealth. Application of absolute and relative risk aversion concepts require one to define "risky" and "secure" assets. Arrow defined secure assets as money. Cohn et al. argue that the classification is an empirical issue.

There seems to be little doubt about the existence of decreasing absolute risk aversion. However, considerable disagreement exists for relative risk aversion. Arrow hypothesized the existence of increasing relative risk aversion on theoretical grounds, while Tsiang argues for its existence based upon empirical observation. Alternatively, Friend and Cohn et al. provide empirical evidence of decreasing relative risk aversion.

Do farm proprietors display decreasing absolute and increasing relative risk aversion? Table 1 provided a balance sheet for the farm sector for selected years. Clearly, wealth of the farm sector has increased substantially over time. If farm proprietors display decreasing absolute risk aversion, one would expect the investment in "risky assets" to increase. This has occurred since all assets, except U.S. savings bonds, have increased in value over time. Likewise, if farm proprietors display increasing relative risk aversion, then the proportion of risky assets should decrease as wealth increases.

If one defines risky assets as all nonmoney assets, then the proportion of risky assets of farm proprietors has increased rather than decreased, consistent with decreasing relative risk aversion.[4] Mere observation of an increasing proportion of risky assets in the portfolio of farm proprietors is not sufficient evidence of decreasing relative risk aversion. Such changes could reflect modifications in transactions demand for money, changes due to changing age and tenancy patterns, etc. However, the observed increase in the proportion of risky assets warrants empirical investigation to determine if farm proprietors display decreasing relative risk aversion. This is especially so given the frequency of the assumption in agricultural studies of a quadratic utility function—a utility function that reflects increasing relative risk aversion.

Risk does not result from instability per se. Rather, it is generated by a discrepancy between actual and expected outcomes. If unstable outcomes do not diverge from expectations, instability should generate no risk responses. Thus, understanding the process by which expectations are formed is a crucial first step in evaluating the magnitude of risk and investment in a risky environment. It seems plausible that the divergence between actual and expected outcomes increases as the degree of instability increases.

Risk Considerations in Studies on Farm Assets and Liabilities

It is useful for discussion purposes to classify empirical studies into four subjective catego-

[4] Defining money as a risk free asset is open to question because the purchasing power of money may be quite unstable.

ries: micronormative, micropositive, macronormative, and macropositive. Distinctions among these categories are not exact, but most studies can be fairly well identified as belonging in one category. Discussion here will focus on the nature of empirical studies in each category that relate to farm assets and liabilities.

Micronormative studies concerning assets and liabilities of individual farm proprietors have been important research topics for some time. Firm growth studies using linear programming (LP) were in vogue during the late 1960s and early 1970s. Studies of this nature relied upon an income or net worth maximization criterion but generally did not include risk considerations in the decision criterion. Some did include liquidity responses as a means of dealing with risk. More recently, greater emphasis has been placed upon quadratic programming (QP) techniques to include considerations of risky investment alternatives. In addition, alternatives to QP that account for risk have been proposed. These include focus-loss constraint programming (Boussard and Petit), chance constrained programming (Charnes and Cooper), and adaptive LP (Chen and Baker). While not all of these techniques have been used to study farm proprietor demand for assets and liabilities, the potential for such study exists.

Considerable effort has been devoted to micropositive models of farm proprietors demand for assets and/or liabilities. Studies range from estimation of demand for a single asset or liability to simulation studies that estimate the entire balance sheet for farm proprietors. Again, risk considerations have been largely ignored. Some micropositive studies (Just 1974) have included risk responses, but these studies have not focused directly on the demand for assets and liabilities.

Recently, Just (1975) proposed an adaptive risk model of the form $y_t = f(x_t^*, z_t^*, u_t, v_t, w_t)$, where y_t is a decision variable, x_t^* is the expected value of variable 1 (price), z_t^* is the expected value of variable 2 (yield), u_t is the subjective variance of variable 1, v_t is the subjective variance of variable 2, and w_t is the subjective covariance between variable 1 and 2. Just suggests that this model reflects "diversifying as well as risk-aversive response to a changing risk structure" (1975, p. 9). While this formulation represents an important first step, particularly for supply response studies, it is useful to recall the effects of changes in wealth on risk aversion. If farm proprietors display either increasing or decreasing relative risk aversion (as opposed to constant relative risk aversion), the proportion of risky assets in the portfolio will change as wealth changes. Consequently, unless relative risk aversion is constant, the level of wealth will influence investment in risky assets. Inclusion of the wealth term to the Just formulation creates no problems, as long as wealth is not highly correlated with other independent variables.[5]

Macronormative models of the agricultural sector have generally focused on production responses to changes in policy variables and, more recently, on resources and the environment. Despite the normative nature of these models, the results are often used to suggest or predict the behavioral responses of farm proprietors. To my knowledge, the literature is void of macronormative models focused toward understanding the portfolio composition of farm proprietors. Macronormative studies have not included considerations of risk. Hazell and Scandizo have provided the theoretical justification for inclusion of risk in such models. But due to lack of knowledge on how to sum utility functions, empirical studies of this nature are not likely for some time.

A large number of macropositive models have focused on farm proprietor investment in a single asset such as land, machinery, or buildings. A smaller number of studies have looked at the entire complement of balance items. Lins and Melichar have provided empirical estimates of balance sheet components, but these studies have not included a simultaneous determination of assets and liabilities as suggested by portfolio balancing theory. More recently, Penson has developed a simulation model that does include a simultaneous determination of the demand for physical and financial assets and liabilities. However, to my knowledge, none of the macropositive studies have included risk considerations in the theoretical framework, although liquidity considerations were subsumed in Penson's work.

While this review of studies of the demand

[5] The wealth term here is initial wealth that will vary across individuals if the study is cross sectional and across time if the study is time series. Expected terminal wealth is likely to be highly correlated with expected prices.

for farm assets and liabilities is brief, one clear fact emerges. Macro models, particularly macropositive models, have not included risk considerations in their theoretical constructs. At least two explanations seem plausible. First, instability in commodity and financial markets has become more pronounced only in recent years. There is likely to be some recognition lag and some lag in incorporation or risk responses into modeling efforts. Efforts to include risk consideration in macropositive models have now been started. Second, Just shows that inclusion of the risk term introduces noise that "prevents accurate estimation of risk term coefficients and biases associated statistics toward insignificance" (1975, p. 13). This bias results from the aggregation process and is likely to be more serious as diversity of the observational units increases. Great diversity exists, particularly for crop and livestock assets of U.S. farm proprietors. Diversity that would lead to aggregation bias would seem to be less severe for financial assets and liabilities; that is, costs of borrowed funds and returns on financial assets appear to be less variable than returns to livestock and crop production.

Concluding Comments

Evaluation of the effects of risk on farm proprietors' demands for assets and liabilities is in the infancy stage. Some micro-oriented studies have made strong advances in developing and testing conceptual frameworks for incorporating risk responses. However, few of these studies have specifically looked at the entire spectrum of investments in physical assets of farm proprietors. No studies, to my knowledge, have considered the effects of risk on the demand for financial assets and liabilities. This result is not surprising because of the degree of stability in capital markets. Yet capital market instability is becoming of greater concern, as evidenced by the recent initiation of futures markets for both long- and short-term interest rates and by the move to variable interest rate loans. Consequently, the effects of financial market instability on the demand for both financial assets and liabilities appear to warrant empirical investigation.

Many applications of risk response behavior of farm proprietors have proceeded without adequate consideration of the process by which expectations are formed. Likewise, there is little empirical evidence of increasing, constant, or decreasing relative risk aversion. Empirical evidence on these points seems crucial to a better understanding of farm proprietors' responses to risk.

As a final thought, researchers should be cognizant of the underlying forces that generate instability in farm commodity and farm capital markets and result in instability in the demand for farm assets and liabilities. If these underlying forces (weather, world food demand, government programs, etc.) generate a new era of stable farm commodity and farm capital markets, what will be the value of research studies geared toward answering questions of instability? Clearly, this is a risk faced by researchers concerned with risk response issues.

Discussion

Bruce L. Gardner

The term instability covers too broad a subject area. Not everything that fluctuates repays study. The papers narrow the topic down in two ways: by limiting the variables whose instability is studied and by limiting the type of change that counts as instability. I have some disagreements in both areas.

What Changes Count as Instability?

Lins makes the pertinent point that instability is important because it creates risk; yet not all fluctuations create risk. It is possible for changing events to be predictable. Unfortunately, it is difficult to separate predictable and unpredictable fluctuations empirically.

All three authors apparently agree that trend changes in a variable should not count as instability. Thus, inflation is equally stable if it occurs at any constant rate in Firch's approach, whether that rate is 10% per year, 5%, or 0. Baker uses the coefficient of variation around trend for his interest rate calculations, which is almost the same as Firch's approach. For Baker, an arithmetic trend counts as stability, while for Firch an exponential trend counts as stability. Lins does not make as definite a commitment, providing measures both of the coefficient of variation around trend and of the coefficient of variation around the mean.

None of the authors provide a convincing rationale for excluding trend, and only trend, from instability measures. In many cases it is reasonable to treat a trend, either arithmetic or exponential, as not contributing meaningfully to instability because the trend can be readily adapted to by economic agents so that change does not imply risk. But some cases do not fit this idea. The interest rate trends in Baker's data do not seem to have been adapted to, since expectation of a continuation of these trends would imply long-term interest rates far higher relative to short-term rates than in the term structure that currently exists. In this case, the coefficient of variation around the mean would probably be a better indicator of instability than the coefficient of variation around trend.

Moreover, if it is reasonable to omit trend, why is it less reasonable to say that slow changes in trend or regular cyclical patterns can also be adapted to, so that variations should be computed around a typical cyclical pattern? Indeed, one can sometimes make a good case for excluding a variation that has no regular pattern but is predictable in advance.

Instability of What?

The reason for interest in instability in agriculture is that it has important consequences for the well-being of consumers and producers of agricultural products. The instability most closely related to well-being is that of the incomes of farm people and of food prices in the budgets of consumers.

Baker's paper does not attempt to say what variation in interest rates has to do with instability in prices, incomes, or other variables. It is not clear, in fact, to what extent he regards interest rate instability as a source of instability in other variables or as an effect of instability. While Lins' paper deals with some of the most interesting effects of instability in agriculture, he does not really come to grips with the question of how commodity market instability in recent years has been connected with farm asset instability or asset values. In Firch's paper, it is not clear why he chooses market receipts as the variable whose instability is to be explained or what implications he thinks instability in receipts has for instability of income.

While the severe space limitation undoubtedly explains some of this problem, nonetheless, I think all three papers are deficient in tying their particular investigations to the ultimate concern with the effects of instability on people's well-being.

Bruce L. Gardner is a senior staff economist at the Council of Economic Advisers.

Particular Criticisms of the Papers

I will concentrate on Firch's treatment of sources of instability, in part because his paper has more substantive analytical content than the others and in part because it leaves so many loose ends.

The approach Firch takes in his first part is to fit regressions of the form $\Delta \ln PQ = b_0 + b_1 \Delta \ln Y + b_2 \Delta \ln Q + b_3 \Delta \ln \bar{P}$, where Q is farm output, P is its relative price, Y is real national income, and $\bar{P}$ is a general price index. Then he uses the regression coefficients as he outlines to calculate the entries in his table 2. I have several comments on Firch's use of this method.

It is natural to distinguish between agricultural and nonagricultural sources of instability in the farm sector, and Firch's approach accomplishes this neatly. In the 1966–75 results, Q, the only agricultural source of instability, has a strikingly small effect on PQ despite its being the most unstable of the independent variables. One reason for this could be that the aggregate elasticity of demand for U.S. farm output is not far from -1, so that PQ does not change much with Q.[1] It would be interesting to see equations that explain farm price instability instead of receipts, where Q should be more important.

The farm output variable has the drawback of being endogenous due to supply response, so that one is not confident of having an estimate of the effects of exogenous output-shifting events such as drought or blight. Although the supply elasticity is undoubtedly small, it may still be troublesome. For example, it is likely that the increased farm output associated with the very large increase in farm receipts between 1972 and 1973 (which dominates the 1966–75 data) was in part a response to increasing demand and not a source of instability at all in the way the decline between 1973 and 1974 in farm output (due to reduce crop yields) was.

There is also a problem with lags between output changes and changes in receipts. For example, the corn blight reduced output in 1970 compared to 1969, but a good part of the resulting high corn prices was received by farmers in 1971. This may be why the Q variable in the 1966–75 corn equation works poorly.

Market receipts are deflated to measure the price of farm products relative to all other goods. While this is appropriate for analyzing the effects of farm output, it would be better to use nominal receipts for regressions including the inflation rate. Inflation creates instability primarily by changing nominal values of commodities, so naturally a relatively small effect of inflation is expected in regressions on the real value of receipts.

The overwhelming importance of real national income in 1966–75 is surprising. The main action in this variable is the large rise in 1971–73 and the decline in 1973–75, which indeed parallels the movement of farm receipts closely. However, before going to great lengths to interpret these results, it should be noted that the opportunity for statistical error is even greater than is usually the case in regression analysis. For each ten-year period there are nine observations on the dependent variable and five degrees of freedom in the regression. Though Firch does not present regression coefficients or their standard errors, the degree of precision required for accurate point estimates would seem very difficult to attain in the regressions he fits.

In the analysis of foreign sources of instability, some regressions use the quantity of exports and some the dollar-mark exchange rate. Both create problems. With respect to exports, when poor foreign crops boost export demand, instability is expected due to higher U.S. farm prices and receipts. But when U.S. crops are large, lower prices and hence increased exports are expected, which are stabilizing just as additions to carry-over stocks are stabilizing. Firch's approach lumps together both stabilizing (endogenous) and destabilizing (exogenous) export changes.

The exchange rate variable is also dubious because the mark-dollar rate, important as West Germany is, still provides the appropriate exchange rate for less than 10% of U.S. agricultural exports (6.7% in 1974–75), and the mark is not a typical foreign currency.[2] A trade-weighted dollar would have been a better choice for the exchange rate variable.

[1] The b_2 coefficient should allow an estimate of the elasticity of demand for agricultural output since $\Delta \ln PQ/\Delta \ln Q = 1 + \eta$, where η is the elasticity of demand. Moreover, the sign of b_2 indicates whether $\eta \lesseqgtr -1$. It is not obvious that $|\eta|$ is far less than unity because of the substantial share of U.S. farm output that is exported.

[2] In particular, during the crucial year 1973 the dollar depreciated much further against the mark than against the yen, Canadian dollar, and other important currencies (Salant).

Also, while macroeconomic trade variables are important, the 1966–75 regressions go too far in excluding real food-sector determinants of export demand (such as foreign production).

While the treatment of stock changes in the individual commodity analysis is imaginative, the theoretical basis for the method used is not clear, nor are the methods of measurement. One problem is that to the extent changes in stocks offset destabilizing changes in other variables, the dependent variable will not vary. With perfect stabilization, the regression coefficients would be zero. The basic idea of looking at the covariance terms between stock changes and changes in output, national income, and foreign demand is an interesting one and worth carrying further. Again, because of the few degrees of freedom, one should not read too much into the particular regression results. The conclusion that CCC stocks have been less stabilizing than free-market stocks is an important hypothesis. But it would be premature to accept it on the basis of the table 7 regressions.

One particular point of apparent inconsistency exists in Lins' paper. In discussing whether his data show risk aversion, Lins takes nonmoney assets as relatively risky. But earlier he finds that the real value of financial assets is no more stable than the real value of physical assets. This is not surprising, since with unstable rates of inflation money may be more risky to hold than land. It would be interesting in Lins' table 3 to see bracketed terms for financial assets such as those presented for physical assets that would measure the coefficient of variation of the price level.

Finally, the authors should be complimented for their objectivity. Issues of instability arouse deeply felt opinions in almost everyone, so that discussion can easily degenerate into an exchange of unsupported assertions and value judgments. This sin these authors have not committed. Still, it is worth keeping in mind the passionate interest aroused by the bottom line issues of who gains and who loses from instability and exactly in what sense instability may be said to be undesirable and what should be done about it. These issues and their policy implications make the research efforts reported in this session practically important and worth pursuing further.

Discussion

B. Delworth Gardner

The authors of these three papers have provided important empirical information to be utilized extensively by the profession and others interested in the instability problem in agriculture. Only one of the three papers, however, attempts to identify and quantify the causal factors associated with instability, and this discussion will deal mostly with that paper. I hope that Firch will interpret this attention to his work as a compliment rather than a criticism. He has provided analytical results to interpret and methodology to evaluate. The instability issues associated with the other two papers will be understood to the same degree only if Lins, Baker, or other scholars take the Firch approach and postulate some causation and test some hypotheses.

I am, however, less than satisfied with the three papers taken as a composite for quite another reason. Moreover, I find the same missing element in nearly all discussions of the instability problem. The missing element is a rationale for looking at instability and why the economist, in particular, has special interest in it. The issues need to be put into some kind of welfare framework that will permit us to gauge the importance of the efficiency and equity impacts of instability and to evaluate the gains and losses that will be incurred by public policy designed to reduce instability.

It has been an article of faith in the profession that fluctuations in prices, income, and wealth create risk and uncertainty that, in turn, produce inefficiency in resource use. This may well be true, but empirical support is quite feeble. Lins correctly points out that even instability per se does not generate risk. Risk is generated by the discrepancy between actual and expected outcomes. But even if instability does produce risk and uncertainty and producers are highly risk averse, it is crucial that the resulting misallocation be quantified if one is to know the social costs of instability.

In the world of reality, the economic issues are very complex. For example, in discussions of the instability problem, it is seldom pointed out that stabilization policies in principle can also create resource misallocations. If real shifts in demand and/or supply occur, then resulting fluctuations in prices are indeed necessary signals to consumers and producers that consumption and production should be altered. To prevent these fluctuations in prices by stabilization devices is to distort the signals and produce misallocation. Empirical studies are needed as well that establish the extent of this misallocation.

Of course, not all fluctuations in prices may result from actual shifts in demand and/or supply. "Noise" is the term that describes the discrepancy between perceived and actual shifts in supply and demand and the transitory and random influences on market prices. Allegedly, eliminating this noise may produce a better allocation of resources. I am uneasy about this simplistic rationale for stabilization policy, however. The trouble is that it is not known by simply observing price changes whether or not these changes are due to actual shifts in demand and/or supply or whether they result from noise. It is not even clear that there is any foolproof way of differentiating between the two. If they cannot be distinguished, then how it is known whether more good than damage is being done by stabilizing?

Moving on to a discussion of the Firch paper, it will be useful to belabor the obvious and present a simple conceptualization of Firch's analytical model. His dependent variable is annual farm marketings, the product of prices and marketed output summed over all relevant agricultural commodities. Fluctuations in marketings can result from two sources—fluctuations in prices and fluctuations in market output. So long as the demand and supply curves are not perfectly

B. Delworth Gardner is the director of the Giannini Foundation, University of California, Berkeley, and a professor of agricultural economics, University of California, Davis.

Giannini Foundation Paper No. 417.

elastic or perfectly inelastic, changes in prices and quantities occur simultaneously. A shift in supply produces a shift in the market price and a shift in the quantity demanded. The critical parameter in this case is the elasticity of demand. A shift in demand causes a shift in the price and a shift in the quantity supplied, and the critical parameter is the elasticity of supply. The greater the elasticity of these curves, the less the price volatility caused by a given shift in the other curve.

Firch's business cycle variable is primarily a demand shifter. It affects marketings through large changes in price and small changes in the quantity supplied, assuming a steep supply curve or vice versa if the supply curve is flat. His foreign trade variable is also a demand shifter and, if significant in explaining fluctuations in marketings, does so in similar fashion conceptually to the business cycle variable. Changes in the farm output variable simply move the equilibrium point along the demand curve, and price changes and quantity changes are in opposite directions. Elasticity of demand determines relative price and quantity changes and whether marketings increase or decrease. Finally, the analytical effects of the inflation variable are much more complicated a priori, as inflation can shift both demand and supply curves depending on what its impact is on relative prices of complements and substitutes in consumption, on relative input prices, and on a host of other factors. Space limitations do not permit a full development.

The point in this brief excursion into price theory is to suggest that Firch's regressions would have been easier to understand and interpret had the variables been specified in these terms. Otherwise, some questions surface. For example, a valid regression analysis postulates "independence" among the explained and the explanatory variables in the sense that they do not measure the same thing or are mutually affected by other variables. In Firch's regression, farm marketings and the business cycle seem to satisfy the independence assumption fairly well, as do farm marketings and foreign trade and, perhaps, farm marketings and inflation, although the identification problem may exist in the case of this variable. But what about the farm output variable? Since market receipts are composed of the product of price and quantity and quantity is farm output, these two variables are related by definition. The question is whether or not there is significant specification bias in the regression results.

There are also other questions about this variable that might be raised. As output shifts, if prices are free to move, a new equilibrium price will be established. Firch's data suggest that the quantity variable is becoming less important over time as an explanatory factor. There are several reasons why this might be so, a priori, and it would be very revealing to know which are empirically significant. Perhaps relative changes in output are not so great as they once were and thus explain less, or perhaps prices have been freer to move in recent years to offset increases in output in determining value of marketings than in earlier decades, dampening the effect of output changes. Finally, as suggested above, the impact of a given output change on marketings depends on the elasticity of demand. Perhaps the demand curve facing American producers of farm commodities has become much more elastic as foreign demand has become more significant in recent years and many more substitutes are available for American-produced commodities. If so, price fluctuations would have been reduced because of a given supply shift. Firch may counter that the significance lies in that the variable is less important than it once was for whatever reason. Granted, but, in judging whether or not it will remain so, it would be helpful to know why.

I have a similar problem with the business cycle variable and the interpretation of the regression results. The message of Firch's 1964 paper was that the business cycle is becoming less powerful over time in producing instability of farm marketings. The alleged reason was the recent implementation of built-in stabilizers that stabilize demand. His data in this paper, however, suggest that the business cycle was quite significant in the last decade. How can this be, since the stabilizers are presumably even more potent now than they were a decade ago? The answer given by Firch is that his results are probably a statistical mirage. Firch believes that this variable is not so significant as his data suggest; he offers the explanation that, because of interdependencies among national economies, the business cycle variable for the United States may be good proxy for foreign demand as well. In other words, there is allegedly high multicollinearity between

these independent variables producing distortion in the coefficients, which might well be true. A simple correlation coefficient between the two could provide evidence.

It is the logic that is not clear. If the two variables are correlated because of interconnectedness in national economies, then foreign demand should have shifted leftward with U.S. demand during the world recession in the last decade. But this is not consistent with the facts. The U.S. recession coincided with huge increases in shipments abroad. Firch then recalls the Russian purchases and the Peruvian fishing problem. Clearly these factors contributed to sales abroad, but they were random influences causally unconnected with business cycle impacts. In fact, these influences, a priori, should have offset some of the decreased demand due to purely business cycle effects. Thus, I am not sure how they could have increased the explanatory power of the business cycle variable.

Firch goes on to postulate a role for a shifting foreign exchange rate in explaining annual changes in farm marketings. I am tempted to agree that the large one-time shift in relative prices of American-produced commodities in world markets resulting from the dollar devaluation produced a large shift in the demand curve. One would have expected a large average annual quantity increase after the devaluation compared to before, but only one first difference would be affected by the devaluation unless a complicated set of lags occurred in supply and/or demand. After the initial shock of the devaluation, it would have been the foreign exchange float that produced the instability of annual farm marketings. This should be called the "Firch effect," as contrasted to the "Schuh effect" that Firch postulates as the important demand shifter.

There is another foreign trade effect that has probably been overlooked in Firch's paper. In 1975, Johnson argued that instability of American farm prices (and indirectly farm marketings) was the result not of shifts in foreign demand or even decline in U.S. foreign exchange rate but instead resulted from the fixed-price policies of U.S. trading partners. Johnson points out that when internal prices are stabilized in some countries by controlling the flow of trade, all of the adjustments in the variability of world supply and demand must be made elsewhere. Stabilized internal prices do not serve the function of influencing either domestic consumption or production. Price elasticity of demand for imports and price elasticity of supply for exports, whichever is relevant, is effectively zero. He goes on to show that the needed adjustments for the 1970s fell upon two groups of countries—the major grain exporters and the low-income countries that imported grain. Johnson may have identified the international source of much of the farm marketings instability. If Johnson is right and if U.S. trading partners do not change their fixed-price policies, the U.S. may be faced with instability resulting from these trade forces for a long time.

I come now to a final question about the Firch data. In his tables 4 and 5, an exchange rate variable was used for 1966–75 to represent the foreign demand shift, but "quantity exported" was chosen as the variable for other periods. Since the variable's contribution to instability is higher for 1966–75 than for the other periods for all commodities (with one exception in each table), one might wonder if this is due to specification differences in the variable rather than real differences among periods. Clearly, the variables are quite different; the exchange rate is a relative price while quantity exported is not.

The paper by Lins contains interesting information on the composition of farm sector balance sheets over time, but I do not quite know what the data mean or how significant the instability problem is. The sector data do seem to imply "absolute risk aversion" and "decreasing relative risk aversion." What this means in terms of efficient resource allocation in decisions is not analyzed. In fact, as pointed out above, Lins suggests that the empirical study results of the effects of risk and uncertainty are indeed meager. Lins has provided a start in providing some of the basic data. It is hoped that he and other researchers will follow up with the more analytical work. I am not necessarily opting for highly sophisticated econometric studies of the Just variety that Lins cites. Less elegant tests of hypotheses of the Firch type are also needed.

The Baker paper is very similar to the Lins paper. Baker's data provide several sets of phenomena that could be explained. One is the variation in the rates of interest charged by various lenders over time. Another is the

relatively greater instability in the wholesale capital markets than in the retail markets. Why do these wholesalers absorb some of the fluctuations arising from credit demand and supply shifts compared to retailers? A third question is the changing proportions of real estate and non-real estate loans made by various lenders.

Baker argues that there is relatively little instability in agricultural capital markets over time, presumably compared to other capital markets in the economy. What is the explanation for this? It might be due to the relatively large proportion of capital funds available to agriculture from stable and subsidized governmental sources, which may have the effect of limiting the fluctuations of competitive private funds.

Notes

The Index of Medical Underservice as a Predictor of Ability to Obtain Physicians' Services

John E. Kushman

This paper presents an evaluation of the Index of Medical Underservice (IMU) as a predictor of a population's ability to obtain physicians' services. Evidence from California's Medi-Cal program shows that the IMU fails to reflect the experience of persons who are nonwhite or rural. An adjustment to the IMU is suggested that may produce a more adequate measure.

The IMU was developed by the Health Services Research Group at the University of Wisconsin. The Department of Health, Education, and Welfare used the IMU to designate areas as underserved for the health maintenance organization program. Priority was given to applications for grants, loans, and contracts where at least 30% of the persons served by a health maintenance organization would come from underserved areas or populations. The index was computed for all U.S. counties, and all counties scoring below the median were designated as underserved. For counties not so designated the computations were repeated for census tracts (metropolitan counties) or census county divisions (nonmetropolitan counties). The same cutoff point was used to choose tracts and divisions for designation as underserved (Health Services Research Group 1975a).

The use of an index to identify underserved populations is increasing. The federal government is attempting to make an index part of an identification scheme to be shared by a number of agencies (U.S. Dep. Health, Education, and Welfare 1975, pp. 47–52). The identified areas are to be targets for coordinated programs. Within the Department of Health, Education, and Welfare (HEW), the Health Underserved Rural Area initiative and the Rural Health Initiative are efforts to coordinate and concentrate the resources of the National Health Service Corps, Maternal and Child Health Services, Neighborhood Health Centers, and other programs in rural areas. Each program has its own eligibility criteria, but funds for coordination of services are available only if the area is underserved according to the IMU.

In recognition of the decreasing availability of primary personal health services, the California legislature passed the Song-Brown Family Physicians Training Act in 1973. The act provides for state support to programs training family physicians, primary care physicians' assistants, and nurse practitioners. The training has to be conducive to practice in "medically underserved rural, multi-cultural, or lower socioeconomic communities" (California Health Manpower Policy Commission, p. 13). The proportion of graduates who actually practice in underserved areas is specifically included as one criterion for evaluating program performance. A provisional list of underserved areas has been compiled by combining the critical manpower shortage areas of the National Health Service Corps, areas designated under the HEW Loan Forgiveness/Loan Repayment Program, and underserved areas of the health maintenance organization program.

Evidently, any bias in the IMU will distort the allocation of resources. If the index fails to capture disadvantages associated with being rural or nonwhite, the resources of a substantial and growing number of programs will be misdirected toward urban dwellers and whites.

Development and Limitations of the IMU

The Health Maintenance Organization Act required the secretary of HEW to designate underserved areas within one year. The time constraint made it impractical to base the designations on objective data regarding health outcomes of health maintenance organizations or health service utilization. In order to meet the requirements of the legislation, it was decided to use a multiattribute utility model to predict how experts would assess the adequacy of health services in an area.

The value, even the necessity, of the IMU arises from the fact that there is no generally accepted definition of medical underservice, and yet experts tend to agree in their evaluation of areas. Consensus expert opinion can be used to designate underserved areas without a determination of whose criteria are

John E. Kushman is an assistant professor of agricultural economics at the University of California, Davis.

Giannini Foundation Research Paper No. 439. The author is grateful to two anonymous referees for helpful comments on an earlier draft and to the California Center for Health Statistics for providing data on Medi-Cal eligibles and claims.

"correct."[1] Furthermore, consensus evaluation appears to be possible on six interrelated constructs: scarcity of health services, ability to obtain personal health services, quantity of health resources per capita in the area, impact of an additional physician on the health status of the population, and ability to obtain physicians' services. One index may serve to predict expert assessments on any of the six constructs (Health Services Research Group 1975c).

Once consensus in evaluating sites had been established, the IMU was constructed. Seventy-two variables thought to be associated with the adequacy of health services in an area were identified. The variables were viewed as direct indicators of adequacy and as proxies for other constructs. The variable list was narrowed to four on the basis of ready availability of reliable data for appropriate population units and on the ability of a combination of the variables to predict expert assessments. The variables eventually used in the IMU were percentage of the population in poverty, percentage 65 years old and older, infant mortality rate, and number of primary care physicians per 1,000 persons.

The four variables were combined into an index using rules explicated by a panel of experts.[2] In order to validate the predictive power of the index, rankings obtained with the index were compared with the actual assessments of local health experts and a national panel of experts. The national panel knew only the four variable values for the sites. The local experts were personally familiar with the sites and were permitted to use any data they wished in forming evaluations. Assessments were compared for sixty-two counties, towns, cities, and groups of census tracts in Michigan, Arizona, and Wisconsin. Fifty-seven experts provided 1,662 assessments of adequacy. Comparison of assessments from the model and the expert panels established that the model predicted expert judgment with acceptable precision (Health Services Research Group 1975a, pp. 15–16). Pearson product-moment correlation coefficients for the predicted and actual assessments were 0.80 or greater with one exception. Spearman rank order correlation coefficients were 0.78 or better, again with one exception (Health Services Research Group 1975b, p. 177).

The IMU's careful development as a consensus evaluation gives it wide acceptability. It predicts quickly and inexpensively the assessments experts would make if they actually visited sites. Predictive validity on a number of dimensions increases the useful scope of the index. There are, however, a number of qualifications regarding the validity of the index.

The first qualification is that the correlation coefficients used as evidence for predictive validity may be artificially inflated by the nonrandom choice of sites or experts. A second qualification is some evidence that the consensus is less strong in evaluating census tracts in metropolitan areas. There is no apparent difficulty with towns, counties, or whole cities. A third qualification is the impossibility of evaluating the results of any intervention with the index. The IMU predicts expert assessments under present institutional arrangements and levels of service. Intervention that alters the arrangements or levels of service would not be reflected in the index (Health Services Research Group 1975b, pp. 177–80).

A more fundamental limitation of the IMU is that it has not been validated as a predictor of actual health status, change in health status, resources in the area, or barriers to care. The index only predicts subjective expert judgments. For many of the six constructs predicted, no objective measure is available or widely accepted. Where objective evidence is available and accepted, the validity of the index must be tested. It is ultimately the objective phenomena that are of interest, not expert opinion.

Evaluation of the IMU and an Alternative

Despite the wide acceptance and usefulness of the IMU, there is concern that it does not adequately capture variations in ability to obtain physicians' services between rural and urban areas and among populations of different racial and cultural compositions. Rural residents may be disadvantaged by distance barriers as well as the restricted practices and out-of-date techniques of older rural physicians. Members of some racial and cultural groups probably receive less adequate service due to provider discrimination and residential segregation, which isolates them from care.[3] Holahan and Davis and Reynolds have presented evidence that nonwhites in Medicaid and Medicare receive fewer physicians' services than whites in the same programs.[4] Davis has shown that among low-income persons nonwhites and rural persons receive fewer services than other persons.

The power of the IMU to predict ability to obtain physicians' services can be evaluated only when the population of interest is specific. The target population for many current and anticipated government

[1] The consensus appears to be limited to persons who share a set of "prototype assumptions." (*a*) Additional personal health services contribute positively to health status. (*b*) A population of low socioeconomic status will benefit more from additional health services than a population of higher status. (*c*) The ability to obtain health services is positively related to socioeconomic status (Health Services Research Group 1975c).

[2] For details of the procedure, see Health Services Research Group 1975a, b, or Nuckton and Kushman. A regression model was also used to obtain an aggregation scheme, but the regression coefficients were unstable across samples (Health Services Research Group 1975b, pp. 176–79). The judge-explicated model was used in program designations.

[3] These concerns have been expressed in instructions to Comprehensive Health Planning Agencies on requesting additions to the health maintenance organization list of underserved areas. They have also been of concern to the California Health Manpower Policy Commission (see also Burnett).

[4] Davis and Reynolds found no significant effect in the Medicare program outside the South.

programs is the very poor and includes persons with handicaps that otherwise qualify them for special assistance. Persons eligible for Medicaid are approximately representative of the target population. Most eligibles have low incomes and qualify for at least one categorical aid program, e.g., Aid to the Blind, Aid to the Permanently and Totally Disabled, or Aid to Families with Dependent Children. In California's Medi-Cal program, about 91% of the eligibles met the requirements for a categorical program aside from the income and property requirements in early 1976. About 84% met the income and property requirements as well (California Dep. Health).

Nationwide, approximately 61% of the poor were covered by Medicaid in 1974 (Davis, p. 129). It is not known how many of California's poor are covered, but the population of eligibles appears to be similar in size and composition to the population of poor and near poor. Medi-Cal eligibles in 1975 were about 12% of the population, while persons with incomes below 125% of the poverty level were around 15% in 1969 (U.S. Dep. Commerce). Ignoring 16% of the eligibles for whom no data are available, it was estimated that in the recent past 70% of the Medi-Cal eligibles have been white and 87% have resided in metropolitan areas.[5] The 1970 census shows persons below 125% of the poverty level income to be 80% white and 89% metropolitan.

Medi-Cal claims per eligible for physicians' services in January and February 1976 were taken as a measure of ability to obtain physicians' services.[6] Claims are an imperfect measure of services to the extent that the number of services per claim varies with specialty and mode of practice (e.g., solo versus group), but they are the best available measure and should reveal systematic effects of significant magnitude. Claims are a preferrable measure to expenditures in the absence of information on prices. Medi-Cal covers almost all physicians' services that are deemed medically necessary by the individual physician without limitations.[7] The most important exclusions appear to be cosmetic surgery and allergy treatments when the problem is not debilitating and psychiatric visits in excess of two per month.

The first empirical question is whether claims per eligible are accurately predicted by the IMU.[8] Using as units of observation the fifty-eight counties of California, the regression estimate is

$$(1)\qquad \frac{Claims}{Eligibles} = \underset{}{-0.1222} + \underset{(4.07)}{0.0052}\,IMU, \qquad R^2 = 0.2286;$$
$$\qquad\qquad\qquad\qquad\quad (1.13)$$

t-values are in parentheses. The equation establishes that the IMU predicts an objective measure of ability to obtain physicians' services. A higher value indicates more adequate services, and claims per eligible are positively related to the IMU. The association is weak, as the regression explains only one-fifth of the variation in claims across counties.

In order to test the hypothesis that the IMU adequately reflects barriers faced by rural and nonwhite persons, regressions including the percentage of the population that are nonwhite and urban as independent variables were used. If the IMU is an inadequate predictor, the new variables should significantly increase the explanatory power of the equation. We would expect the percentage nonwhite and the percentage urban to be related negatively and positively to claims, respectively. The new equation (t-values in parentheses) is

$$(2)\quad \frac{Claims}{Eligibles} = \underset{}{0.0557} + \underset{(1.67)}{0.0023}\,IMU - \underset{(1.50)}{0.0029}\,Nonwhite + \underset{(4.15)}{0.0016}\,Urba$$
$$\qquad\qquad\qquad\qquad

rved. Program resources may then be diverted to eas that are underserved but do not represent able practice opportunities. Ultimately, the failure o identify many underserved areas may lead to negative program evaluations. It may seem extremely difficult to redress the disadvantages of nonwhites and rural persons that prompted the programs largely because the operating procedures direct resources away from those groups.

Faced with evidence that the IMU has limited usefulness in comparing areas of different rurality and racial composition, the policy maker has a number of options, each of which involves some sort of ad hoc procedure. The most obvious course is to use the IMU to choose only among areas that are similar in rurality and racial composition. There are difficulties, however, in deciding what cutoff value to use in each type of area, in forming a classification, and in allocating resources among the classifications.

Another alternative is to use only the objective nformation of claims per eligible. Table 1 juxtaposes he IMU and claims-per-eligible rankings for California counties. The rank order correlation between the rankings is only 0.45. Policy decisions usually take the form of declaring counties in the lower half or lower quartile to be underserved. Sixty-two percent of the counties below the median IMU are also below the median of claims per eligible. For the lower quartile the figure is 57%.

It may be objected that the subjective information of the IMU should not be entirely ignored. The IMU is based on an interdisciplinary consensus and may add information about persons not eligible for Medi-Cal. These objections are more compelling for programs requiring wide public support to be successful and having a relatively broad target population. A way around the difficulties is to combine the specific and objective evidence from claims per eligible with the more general and subjective information of the IMU to form a new index. Assume, for instance, that the effects of rurality and race are proportionally the same for all elements of the target population as for Medi-Cal eligibles, while other effects are adequately predicted by the IMU. A hybrid index can be calculated by the following steps: (*a*) choose a "standard county" arbitrarily; (*b*) for each other county find the fraction of claims per eligible predicted by equation (2) that is due to the difference between rurality and racial composition in that county and the standard county; (*c*) if claims would be higher with the characteristics of the standard county, deflate the county IMU value by the fraction found in step (b); if claims would be lower, inflate; and (*d*) compare the new hybrid index values that have been inflated (deflated) in accordance with the proportional advantage (disadvantage) of each county relative to the standard county.

A hybrid index for California counties according o the rules above was computed. The ranking is iven in column three of table 1. The rank correlaon between the IMU and the new index is high at

[a] In case of ties, ranks have been randomly assigned to avoid spurious correlation due to alphabetic ordering.

0.87. The correlation with claims per eligible is 0.50. Seventy-six percent of the counties that were below the median on the IMU are also in the lower half with the hybrid index. For the lower quartile the rankings share 86% of the counties. Compared to claims per eligible, the hybrid also retains 76% of the counties below the median but keeps 57% of the lower quartile counties. In a policy context rankings are substantially different between the first and third columns, as one-fourth of the counties below the median (seven counties) change between columns.

The hybrid index is an apparent solution to the problem of special barriers to physicians' services associated with rurality and race. More or less weight can be given to the objective evidence as seems appropriate. There are, however, a number of cautions that must be observed. Most obviously, the proportional adjustments require that differences in utilization reflect barriers rather than tastes and that the entire target group be affected by factors associated with rurality and race in the same (or at least approximately the same) proportion as Medi-Cal eligibles. Neither assumption is self-evident or established by empirical evidence. Use of the hybrid index depends on a judgment that the assumptions are reasonable.

A less obvious consideration, but one that is crucial, is that proportional adjustment requires the IMU to be on a ratio scale.[10] The techniques used to construct the index permit the presumption of an interval scale. The statistical insignificance of the constants in equations (1) and (2) is consistent with a ratio scale, but more evidence would be necessary to establish it.[11]

Conclusions

The Index of Medical Underservice is a statistically significant predictor of ability to obtain physicians services under California's Medi-Cal program, but it does not predict accurately. In particular, the IMU fails to identify rural and nonwhite persons who are disadvantaged. These findings can be generalized to the entire California population of poor and near poor.

Important federal and state programs use the IMU to locate populations that are disadvantaged in access to physicians' services. More programs will be using an index approach in the future. Bias against rural persons and nonwhites in the index will cause resources to be allocated away from those persons. As a result, the programs may fail to redress the inequities of other allocative mechanisms and to identify many viable practice sites.

A hybrid index was constructed that combines objective information on Medi-Cal utilization with the subjective information of the IMU. Depending on the plausibility of the assumptions involved, the hybrid index will correct for rurality and race and allow comparisons across types of populations. A ranking of counties under the hybrid index shows little overall difference from the IMU ranking, but there is a substantial difference in the lowest quartile counties that are most relevant for policy. Further evidence on the validity of a hybrid index would be useful, since it may provide an operating rule without the biases of the IMU.

[*Received June 1976; revision accepted October 1976.*]

[10] If the IMU is on an interval scale, the error in equations (1) and (2) has a nonzero mean, the coefficient of the IMU times the difference between the arbitrary zero of the interval scale and a meaningful zero. The estimate of the constant term is biased. The estimates of the coefficients still have desirable properties.

[11] Another caution is that the California experience may not be representative of the national experience. For instance, the correlation coefficient between percentage nonwhite and percentage urban is 0.53 for California counties but only 0.18 for the counties of five other states selected randomly. Obviously, the specific equations reported here can not be used in other states.

An Operational Approach to Multiple Objective Decision Making for Public Water Resources Projects Using Integer Goal Programming

Walter P. Neely, Ronald M. North, and James C. Fortson

Traditional decision-making techniques, such as linear programming, can only optimize one criterion. A variation of linear programming called integer goal programming is proposed as a quantitative approach to integrate multiple objectives in the selection and scheduling of federally funded water resources projects. The deviations from target levels of both economic and environmental objectives may be minimized by using integer goal programming in the evaluation of projects under the proposed multiple objectives. Integer goal programming has the added advantages of permitting decision makers to specify and to change the priorities given each goal and to select only complete rather than partial projects in multiple period funding of multiple objective projects.

The Multiple Objective Problem

The federal water resources project investment decision process has historically maximized one objective, economic efficiency. Recent procedures require that the decision process be extended to at least a second objective, environmental quality. The primary set of objectives recommended by the U.S. Water Resources Council (WRC) and adopted by the Executive Branch include the enhancement of national economic development and the enhancement of the quality of the environment. Other objectives stressed by the WRC are social well-being and regional economic development. However, these two items are recognized only in "accounts" that are believed to be sufficiently included in the encompassing objectives of national economic development and environmental quality (Cicchetti et al., WRC). The four accounts (one quantified and three subjective) provide an effective display of nonmonetary benefits and costs, especially in the subjective areas of environmental quality, social well-being, and regional impact.

The enhancement of national economic development is achieved by "increasing the value of the nation's output of goods and services and improving national economic efficiency" (WRC, p. 24781). Traditionally, this objective was measured using expected economic benefits and estimated costs of resources in terms of dollars (present value basis). The benefit-cost ratio from these estimates was the criterion used by federal agencies to select and recommend projects.

The environmental quality objective is achieved by "the management, conservation, preservation, creation, restoration, or improvement of the quality of certain natural and cultural resources and ecological systems" (WRC, p. 24781). Traditionally, this objective has been treated subjectively, if at all. However, the requirement for environmental impact statements under the National Environmental Policy Act for all federal water resources projects has provided the impetus to formulate this objective more quantitatively. The WRC suggests an equal weighting for the two objectives, which requires equivalent quantification and satisfactory rather than maximum solutions.

Goal Programming Methodology

The goal programming (GP) technique, a form of linear programming (LP), has been developed for multiple objective decision making in business by Charnes and Cooper, Ijiri, Mao, and Lee. Applications of the technique in agriculture, forestry, and natural resources have not been widely developed except by Neely, North, and Fortson in water resources. Candler and Boehlje described the application of traditional linear programming to the problem of achieving multiple goals when a preferred goal was subject to specified constraints. However, goal programming allows one to consider multiple goals and to eliminate the unfeasible solutions often obtained through linear programming.

In the GP objective function, one seeks to mini-

Walter P. Neely is an assistant professor in the Department of Business Administration, University of North Carolina at Greensboro, Ronald M. North is an associate director of the Institute of Natural Resources and James C. Fortson is an associate professor in the School of Forest Resources, University of Georgia.

mize the deviation from the goals. Goal programming requires only striving to attain the goal (i.e., "satisficing"), not constraining the solution to the achievement of the goal. The GP objective function may be described as follows: $\min z = \sum_i w_i^+ y_i^+ + \sum_i w_i^- y_i^-$, where y_i^+ is the deviation above (overachievement of) the ith specified goal level and y_i^- is the deviation below (underachievement of) the ith specified goal level for each goal. The w_i^+ and w_i^- are penalties or weights attached to the goal deviations. The goal weights and/or the target goal levels may be used to rank the goals according to the relative importance of each goal.

If all goals are considered equally important, the weights might not be equal because the unit of measure as well as the relative value of each goal might implicitly weight each goal. In order to counter the implicit weighting differences, weight adjustors may be required to equalize the weight assigned to one goal with that of another.

In order to give greater weight to the national economic development goals over the environmental quality goals, the national economic development set of weights would be used. Similarly, environmental quality weights are used when emphasizing that goal. The product of the weight adjustor and the goal level deviation (w^+y^+ or w^-y^-) for more important goals must always be greater than the products corresponding to the less important goals. The goals with higher weights are therefore satisfied in preference to the lower weighted goals. Of course, specifying high target levels for certain goals is similar to assigning high weights, since the products of the weights (w) and the deviations (y) are minimized.

The various goals incorporated in the GP model may be represented by

$$\sum_{j=1}^{m} AI_j X_{ij} + y^- - y^+ = AIG,$$

where AI_j is some goal contribution by project j, X_{ij} is the decision variable or the proportion of project j accepted in period i, and AIG is the goal level for goal AI.

In addition to the goals there may also be several environmental constraints in the GP model. Budgetary constraints may be represented in the GP model in the same form as in an LP model, or they may be represented as goals. Similarly, the integer constraints are implicit for the integer programming (IP) model summarized in table 1. The IP variant eliminates the problem of partial project completions under conditions of annual budget limitations and new project introductions into the portfolio.[1]

The Empirical Analysis of Multiple Objectives

The data used to test the GP technique were the benefit-cost data prepared by the Tennessee Valley Authority (TVA) for their water resources projects for 1965–73. Benefits were calculated by TVA ac-

[1] When integer constraints were not imposed, almost every accepted project was either spread intermittently over several years or only partially completed. Although the GP-IP solution eliminated the fractional projects, it greatly increased computational time due to the large number of integer variables (220). The solutions, the project portfolio, and construction schedule were changed significantly when the GP-IP method was used. In order to obtain an optimum or near optimum solution, the computer processing unit time on an IBM 360-65 system was approximately one hour. The program used was the IBM program product MPSX-MIP, which utilizes a branch and bound algorithm.

cording to accepted procedures. Projects that were predominantly for power were excluded from this analysis (Neely).

The budget levels for the 1965–73 planning period constitute a set of economic constraints that must be satisfied. The budget level for each year tends to be a binding constraint for the programming model. While the budget level may be predicted with some accuracy, any unpredictability of the budget level does not detract from the validity of the GP technique as a decision-making aid.

The final data assumption necessary to make the model operational deals with the appropriate discount rate. During the planning horizon (1965–73) the WRC discount rate rose from 3-1/8% to 6-7/8% (WRC, p. 24822). While different discount rate assumptions were tested, the 3-1/4% rate, under which most of these projects were originally evaluated, was used in this study to avoid any bias resulting from variances in the discount rate.

There are two goal assumptions necessary to make the GP model operational. Goal weights and goal levels must be specified for each goal. Goal weights for each component are required to give greater priority or to equalize priority for each component goal such as net present value, hydroelectric power, water quality, etc. Each of the objectives, and therefore each of the goals, is initially weighted equally by the weight adjustors to comply with the implicit WRC suggestion of equality (WRC).

The goal level assumption is critical to the final solution and is a policy decision relating to the amount or level of each goal. Each goal level must be specified with care because the set of specifications may be as important as the budget level forecast. An appropriate set of goal levels as well as goal weights may be approximated subjectively by an agency, by experienced professionals, or by a political process. The requirements of specifying goal levels and weights is a weak point in the goal programming method. However, this specification of goals is implicitly accomplished in the present decision process without the advantage of organized data. Goal programming forces an explicit consideration of each goal and puts that goal level and weight into a quantitative framework.

The effects of assigning equal weights to the national economic development and environmental quality objectives are reflected in the differences in the projects selected in the portfolio (table 2). The goal levels assumed favor either the national economic development or the environmental quality

Table 3. Annual Portfolios Selected When the Goal Levels and Goal Weights Favor Either National Economic Development (NED) or Environmental Quality (EQ)

Note: Perfect foresight of projects, the actual budget, and a 3-1/4% discount rate are assumed for the 1967–77 planning period. (U), (B) and (D) refer, respectively, to the project units of the Upper French Broad River, the Bear, and the Duck system projects. Project columns 1 and 3 correspond to data columns 1 and 3 of table 5.

[a] The portfolios selected by the programming approaches fully utilize the budget including that proposed for 1974–77, while the actual projects selected leave a credit balance of $0.983 million based on original costs.

[b] The goal level was $105 million for the net present value goal. The other levels (specified and attained) are shown in table 5.

[c] The "actual" projects for 1974–75 are proposed by the TVA to occur during those years.

[d] Integer optimum not proven due to extended computer processing unit times; result is infinitely near optimum.

objective in each respective column. The most significant result of the differences between goal levels is in the timing of project selection. Many of the same projects were chosen under each preferred level. However, different construction schedules were suggested for the different goal level preferences, national economic development or environmental quality (tables 2 and 3).

The effects of giving either national economic development or environmental quality greater weight instead of equal weight are shown in table 3 for both preferred goal levels. The national economic development preferred (weight and goal level) portfolio contained projects concentrated in the early years of the planning period, while the environmental quality preferred portfolio was more evenly distributed over time. The latter emphasized the Upper French Broad River (UFBR) project with thirteen of the sixteen proposed units selected.[2] Only eight proposed UFBR units were chosen in the national economic development preferred portfolio. The large Tims Ford project was absent from the environmental quality portfolio but included in the other. Different goal priorities or different goal levels result in very different portfolios and/or project schedules. Such divergent results from varying the goal levels point out the great need to use the GP-IP technique or an equivalent method to integrate multiple objectives into the water resources project planning and decision-making process.

The differences in the specifications of a weighted objective (for either national economic development or environmental quality) and the specification of equal weight may be examined by comparing the corresponding columns of tables 2 and 3. The resulting portfolio net present value was about $98.5 million when national economic development was weighted greater than environmental quality (assum-

[2] The problem of sequencing multiunit projects was not treated because the data were insufficient in this regard. While the projects selected might change if Krutilla's or Morin's methods of one-dimensional sequencing with discrete discount rates had been utilized, the validity of the goal programming approach remains unchanged.

Table 5. Goal Levels Actually Attained, Specified, and Attained by the Model Using the Goal Programming Approach

Objective/Goal	Actual Level Attained by TVA	National Economic Development Specified Goal Level	Goal Level Attained With GP-IP Model[d]
		Million $[a]	
National economic development			
Net present value[b]	73.780	105.00	92.110
Power[b]	0.552	0.28	0.380
Power (kilowatts)[b]	264.000	200.00	200.000
Navigation	0	0.50	0.531
Flood control	1.763	2.50	2.502

Redevelopment[b]	0.113	0.05	0.239
Expansion[b]	1.616	1.00	1.099
Increased land values	0.123	0.10	0.105
Prevented flood damage	0.194	0.15	0.168
Shoreline development	1.127	1.00	1.062
Recreation (mil. user days)[b]	2.606	2.00	2.189
Water supply	1.000	0.80	0.745
Quality of the environment			
Area inundated (acres)	51,310.000	35,000.00	28,079.900
River miles lost (miles)[c]	197.200	266.00	111.350
Reservoir shoreline (miles)	1,105.000	687.00	601.000
Water supply[b]	0.386	0.60	0.996
Fish and wildlife[b]	0.501	0.40	0.372

Note: Planning report knowledge, the actual budget, NED preferred goal levels, and equal goal weights are assumed. Data columns 1 and 3 correspond to project columns 1 and 3 of table 4.

[a] Except as otherwise specified.

[b] Overachievement in these goals was not penalized (GP-IP).

[c] Underachievement in river miles lost was not penalized (GP-IP).

[d] Integer optimum not proven due to extended computer processing unit times, but result is infinitely near optimum.

ing the former's goal levels). When both shared equal weight (assuming national economic development goal levels), the resulting net present value was about $92.1 million. The national economic development preferred (by goal weight and level) portfolio included the large Tims Ford project, while the equally weighted (by goal weight) portfolio contained the smaller Cedar unit of the Bear project. There are significant differences between the portfolios chosen in this GP-IP model and those actually chosen by TVA. Aside from the differences in projects and project schedules, a very striking difference is the lower portfolio net present value that resulted between the actual selection of projects using the present benefit-cost ratio method and the proposed portfolios. The actual selection of projects resulted in a loss of net present value of over $20 million compared with a GP-IP portfolio for projects selected during this period. This comparison of the actual projects selected by the TVA with the projects selected by the GP-IP approach suggests the superiority of the proposed method in future project planning decisions for optimization of both national economic development and environmental quality objectives (table 4).

Other differences between goal attainment may be examined from data in table 5. The national economic development goal levels are shown in the second data column, while the goal levels attained using GP-IP are shown in the third data column. The actual levels attained are shown in data column 1. Note the differences between the TVA actual results and the GP-IP results in the environmental quality goals of area inundated and water quality. The national economic development goals of net present value and flood control provide additional examples. The very significant differences between data column 1 and data columns 2 and 3 suggest that even assuming a variance between the goal levels specified for this research and the actual (implicit) goal levels specified (and achieved) the GP-IP approach appears to be superior to the present subjective decision approach.[3]

The use of the goal programming approach enabled the selection of a combination of projects from which most of the goals are higher than the actual levels. Not only do those with decision inputs have

[3] Regional economic development goals were also included in the model but given lower priority (Cicchetti et al.).

difficulty in selecting goals and calculating trade-offs, but the current complexities in decision making may lead to relatively low benefits on all fronts. By systematically considering the alternatives through formal programming, these undesirable consequences may be minimized.

Summary

The goal programming method provides a basis for an operational approach to multiple objective decision making. The best indicator of the value of the proposed goal programming approach is to test and develop it on a regional or even on a national basis for each construction agency or for the total of all water resources budgets. Such tests can provide practical suggestions of the expected economic, environmental, and social benefits and costs of decisions regarding the selection of projects for funding and construction.

While there are many other factors that could have affected the actual choices of projects (especially political motivations, lack of information regarding future investment opportunities, and budget uncertainties), the GP-IP model could have improved the decision-making process. The goal programming approach is capable of incorporating environmental, regional economic, and national economic factors. Political factors and other qualitative parameters of a social and environmental nature can be built into the model as constraints or as additional goals. The capacity to make trade-offs for different goals in the GP-IP model and to observe the changes in costs, benefits, and net values that result makes this model a powerful decision-making tool in the water resources project selection processes.

To improve the effectiveness of the goal programming technique, significant improvements in both measurement methods and parameter estimation are required. The specification of goal weights and levels is also of great importance to the outcome using the GP-IP approach. Sensitivity analysis may be used to determine the effects of various goal weights. Goal levels may be better estimated through the use of parametric programming. The GP-IP approach offers significant potential for future research and practice as long as improvement of the multiple objectives for planning and evaluating water resources investments remains a viable policy.

Farmers' Expectations, Risk Aversion, and Market Equilibrium under Risk

P. B. R. Hazell and P. L. Scandizzo

Hazell and Scandizzo (1975) have argued that, when production is risky, competitive markets may no longer be socially efficient and important welfare gains may be obtained through policies aimed at optimally distorting market prices and quantities from their equilibrium values. Newbery has since shown, however, that these results stem in large part from the assumption that farmers base their decisions each year on anticipated prices formed independently of anticipations about yield.

The purposes of this paper are threefold: (*a*) to show that farmers may hold rational expectations in the Muthian sense if they make direct forecasts of revenue per acre (instead of separate price and yield forecasts); (*b*) to show how, if rational expectations are assumed, competitive market equilibria can be simulated in sectorwide mathematical programming models; and (*c*) to illustrate these results with a linear programming model of agricultural production at a subsector level in Mexico.

Rational Expectations and Market Equilibrium

Consider the following market structure:

(1) Demand function: $D_t = a - bP_t$,

(2) Supply function: $S_t = \frac{\lambda}{\mu}\epsilon_t R_t^*$,

(3) Market clearing condition: $D_t = S_t$,

and $E(\epsilon_t) = \mu$, $V(\epsilon_t) = \sigma^2$, and $E(\epsilon_t \epsilon_{t-1}) = 0$ for all t, where R_t^* is the per acre revenue anticipated by producers at the time of making production decisions, P_t is market clearing price, ϵ_t is stochastic yield with mean μ and variance σ^2, and a, b and λ are positive constants.

Let R_t^* initially be set as the naive forecast in which producers simply project last year's per acre revenue, $R_t^* = P_{t-1}\epsilon_{t-1}$; that is, a naive cobweb model, but one defined in revenue rather than in price. Despite this simple formulation, R_t^* is nevertheless a rational expectation in that it maximizes the expected value of realized (*ex post*) consumer's and producers' surplus.

To show this, first solve for the market clearing price P_t:

$$P_t = \frac{a}{b} - \frac{\lambda}{b\mu}\epsilon_t(P_{t-1}\epsilon_{t-1}). \tag{4}$$

Multiplying through by ϵ_t and taking expectations yields

$$E(P_t\epsilon_t) = \frac{a\mu}{b} - \frac{\lambda\mu_2}{b\mu}E(P_{t-1}\epsilon_{t-1}), \tag{5}$$

where μ_2 is the second moment of ϵ around zero.

The market will converge to an equilibrium in mean price if $E(R_t^*) = E(P_t\epsilon_t)$ converges. Using equation (5), if $E(P_t\epsilon_t)$ converges, then the limiting value is[1]

$$\lim_{t\to\infty} E(P_t\epsilon_t) = \frac{a\mu^2}{b\mu + \lambda\mu_2}. \tag{6}$$

Using equation (6) and taking the limit of the expected value of equation (4), one obtains

$$\lim_{t\to\infty} E(P_t) = \frac{a(b\mu + \lambda\sigma^2)}{b(b\mu + \lambda\mu_2)}, \tag{7}$$

which is the value of expected market clearing price in equilibrium and is identical to the expected market clearing price in Hazell and Scandizzo's optimally distorted market (1975, equation (12)).

This simple example can easily be generalized to weighted linear lagged forecasts of per acre revenue. The key result still holds that revenue expectations, unlike price expectations, are rational in the sense that they lead to a market equilibrium in which social welfare is maximum. Of course, which of the two types of expectations behavior is most relevant is a purely empirical question and one that has not been specifically addressed in the literature. Conventional wisdom among economists tends to support the price forecasting model, in which case competitive markets are not efficient. But, to the extent that

P. B. R. Hazell and P. L. Scandizzo are economists in the Development Research Center, International Bank for Reconstruction and Development, Washington, D.C.

The International Bank for Reconstruction and Development is not to be held responsible for the views expressed in this paper.

[1] This value has a direct relationship to the optimal anticipated price $E(P^*)$ obtained by Hazell and Scandizzo (their equation (12)). In fact, $E(P^*) = \lim E(P_t\epsilon_t)/\mu$. This is the price that farmers should anticipate if social welfare is to be maximum.

individual yields and prices are negatively correlated and farmers do or can be persuaded to use revenue expectations, the need for market intervention policies diminishes.

Mathematical Programming Models of Market Equilibrium

An increasing number of formal agricultural sector models are now being built using mathematical programming techniques. Many of these models are also structured to provide the perfect competition solution to all product markets when both prices and quantities are endogenous. As such, these models are necessarily premised upon assumptions about the underlying nature of farmers' expectations and market behavior, and the results of the previous section raise interesting questions about appropriate model specification when production is risky.

To illustrate the approach, consider a simple model of annual crop production based on a single aggregate farm facing the linear demand structure $P = A - BWX$. Assuming risk averse behavior of the mean standard deviation type, the quadratic programming formulation of the model maximand can be written as[2]

$$(8) \quad \max \Pi = X'W(A - 0.5BWX) - C'X - \phi(X'\Gamma X)^{1/2},$$

where X is an $n \times 1$ vector of crop acreages grown, W is an $n \times n$ diagonal matrix of crop yields per acre, C is an $n \times 1$ vector of costs per acre, A and B are $n \times 1$ and $n \times n$ matrices of demand coefficients, respectively, Γ is an $n \times n$ covariance matrix of crop revenues (price times quantity), and ϕ is a suitable average of individual farmers risk aversion parameters.

Hazell and Scandizzo (1974) show that the market equilibria simulated by this model maximand correspond exactly to the competitive equilibria that would be arrived at if production is lagged and farmers act on the basis of price expectations. Such market equilibria are inefficient when social welfare is measured as the sum of expected values of the realized (*ex post*) consumers' and producers' surplus. Thus, while equation (8) is the correct model maximand for simulating competitive market equilibria given underlying price expectations behavior, it is not the appropriate maximand when farmers act on the basis of revenue expectations. In fact, given the results of the previous section, the appropriate model maximand for revenue expectations behavior must be the maximand that also gives the optimally distorted solutions to all markets. This maximand is the sum of expected values of the realized (*ex post*) consumers' and producers' surplus.

[2] The maximand requires that the demand matrix B be symmetric.

Algebraically, the appropriate maximand for the sector model becomes

$$(9) \quad \max E(SW) = E[X'N(A - 0.5BNX)] - C'X - \phi(X'\Gamma X)^{1/2},$$

where N denotes the diagonal matrix of stochastic yields such that $E(N) = W$. This maximand differs from equation (8) in that the first term, $E[X'N(A - 0.5BNX)]$, is the expected value of the sum of the areas under the demand curves. Comparing equations (9) and (8), it is evident that the two maximands differ only by the term

$$(10) \quad 0.5X'V(NBN)X = 0.5 \sum_{i=1}^{n} \sum_{j=1}^{n} x_i x_j \sigma_{ij} b_{ij},$$

where $V(NBN) = E(NBN) - WBW$ is a variance-covariance matrix of weighted yields with ijth element $\sigma_{ij} b_{ij}$, and σ_{ij} denotes the covariance of yields between crops i and j, and b_{ij} denotes the cross-demand coefficient. Given that equation (9) is accepted as a useful welfare function, this term is a direct measure of the social costs of market inefficiency (and hence the gain from government intervention) that arises when farmers plan on the basis of price rather than revenue expectations.

The maximand defined in equation (10) does, in fact, provide the solution corresponding to the competitive market equilibria that would be attained if farmers planned on the basis of revenue expectations. Let the constraint set over which equation (9) is maximized be linear, and denote it by $DX \leq b$. Then, the Lagrangian for the problem is

$$(11) \quad L = X'WA - 0.5X'E(NBN)X - C'X - \phi(X'\Gamma X)^{1/2} + v'(b - DX),$$

where v is a vector of dual values. Apart from the feasibility conditions $DX \leq b$, the necessary Kuhn-Tucker conditions imply

$$(12) \quad WA - E(NBN)X \leq C + \phi\Gamma X(X'\Gamma X)^{-1/2} + D'v.$$

From the assumed demand structure, the vector of market clearing prices in any one year is $P = A - BNX$. Multiplying by the diagonal matrix of yields N, the vector of per acre revenues R is then $R = NP = NA - NBNX$. Taking the expected value, $E(R) = WA - E(NBN)X$. But this is the left-hand side of equation (12), so that at optimality expected revenue per acre must be equal to or less than marginal cost for each activity. Complementary slackness conditions require that equation (12) hold as a strict equality for all nonzero X_j, in which case expected marginal revenue equals marginal cost at optimality.

The optimal solution is the required market solution if farmers equate expected marginal revenue with marginal cost at equilibrium. Given $E(y) - \phi S(y)$ utility, and revenue expectations R^* that, at

equilibrium, satisfy $E(R^*) = E(R)$, then the appropriate farm planning problem is max $U = E(R)'X - C'X - \phi(X'TX)^{1/2}$ subject to a set of linear resource constraints that are again denoted by $DX \leq b$. It is a trivial task to show that the necessary Kuhn-Tucker conditions for this problem lead to the same result as in equation (12) and that complementary slackness conditions again require that expected marginal revenue equals marginal cost for all nonzero X_j.

An Illustrative Application in Mexico

An agricultural sector model (CHAC) already exists in Mexico (Duloy and Norton 1973) and provides a suitable basis for comparing the equilibrium effects of price versus revenue expectations behavior. CHAC is a linear programming model that encompasses the supply—domestic and imported—and all demands—domestic and export—for thirty-three short-cycle crops. It does not include livestock, forestry, or long-cycle crops. The model is an aggregate of regional submodels, which are linked through a national market structure (domestic and foreign) and by some common resource constraints. CHAC is a static equilibrium model and provides the perfect competition solution to all markets for both prices and quantities through use of the kind of maximand detailed in equation (8) under the assumption that farmers are, on the average, risk neutral ($\phi = 0$).

To keep this study within manageable limits, a smaller version of CHAC was created that includes only selected areas of irrigated land. These selected areas represent eight of the more than one hundred administrative districts of the Mexican Ministry of Water Resources. They are not contiguous districts but are scattered throughout the arid agricultural areas of Mexico. The Pacific Northeast area includes the districts of Culiacan, Comision del Fuerte, Guasave, Rio Mayo, and Santo Domingo. The North Central area includes the Ciudad Delicias and La Laguna districts, while the Northeast area includes only the Bajo Rio San Juan district. Taken together, the eight districts account for significant shares of the national production of cotton, tomatoes, dry alfalfa, rice, soybeans, and safflower (see table 1). The average district cropping patterns for the years 1967–68 to 1969–70 are given in table 1 and exclude a small percentage of land devoted to crops that are not included in the models. Crop production is almost entirely dependent on irrigation in all eight districts, and any small areas of rainfed land have been excluded.

In total, the eight district models cover 99,000 farms of an average size of 5.8 hectares (table 1). For modeling purposes, each district is treated as a single large farm. The farms are thought to be sufficiently homogeneous so that this procedure is unlikely to lead to any serious aggregation bias. The model's activities provide for the production, in each district, of the crops grown by that district, each with a choice of three mechanization levels and two planting dates. A set of labor activities provides flexibility in selecting seasonal combinations of family and hired day labor. Family labor is charged a reservation wage of one-half of the hired day labor rate. Purchasing activities provide for the supplies of

mules, machinery, and irrigation water. Seasonal constraints are imposed on land and labor, and an annual constraint is imposed on water supplies. Technical coefficients and costs are taken at 1967–68 to 1969–70 average levels. The model's constraints are also based on this period. Average yields are based on the six-year period 1966–67 to 1971–72, and risk parameters were estimated from time-series data spanning the period 1961–62 to 1970–71.

The district models are linked in block diagonal form and integrated into an aggregate market structure, similar to that in CHAC; that is, the market comprises linear domestic demand functions of the form $P = A - BWX$ and has import and export possibilities at fixed prices.[3] The domestic demand curves have the same national price elasticities as in CHAC but are located at mean output levels appropriate for the eight district aggregates. Export and import constraints are also prorated according to the ratio of output from the eight districts to national output for each product. Finally, the model structure was changed from that of CHAC by introducing risk averse behavior. More specifically, farmers are assumed to maximize $E(y) - \phi S(y)$ utility.

The resultant model was solved for competitive equilibria solutions to all product markets corresponding to price and then revenue expectations behavior. This was achieved by using the two maximands defined in equations (8) and (9).[4] In both cases, the aggregate risk aversion parameter ϕ was varied in order to evaluate the effects of different levels of risk averse behavior on the model's solutions.

Tables 2 and 3 show the domestic price solutions to the two models for different values of ϕ. These values are the expected market clearing prices in equilibrium and are obtained as dual values from the model solutions. Since there is obviously a one-to-one relationship between the market prices and the total production of each crop sold in the domestic market, differences between price solutions also reflect differences in production.

In general, the revenue expectations model leads to higher domestic prices and, hence, to lower production for the domestic market. This effect is particularly pronounced in the case of chilies, while wheat and maize provide the only significant excep-

[3] To approximate cross-elasticity relationships in demand, the crops are classified into demand independent groups (see tables 2 and 3), and linear substitution is allowed between products within each group as rates fixed by average 1967–68 to 1969–70 relative prices. For a more detailed description, see Duloy and Norton (1973, 1975).

[4] In both cases solutions were obtained through linear programming, using the linearization techniques of Duloy and Norton (1973, 1975), and Hazell (1971).

Table 3. Price Solutions for the Revenue Expectations Model with Various ϕ Values (Pesos per Ton)

	Values of ϕ					Base Period Actuals
	0	0.5	1.0	1.5	2.0

Cucumbers	579	702	291	108	6	590
Social welfare (*billions of pesos*)	4.48	4.27	4.10	3.96	3.85	

tions. This is to be expected, since the solutions to the revenue expectations model correspond to the optimally distorted prices of the Hazell-Scandizzo model. Hazell and Scandizzo (1975) showed, in the single-product case, that the optimal market distortion involves a cutback in production compared with the level in a price expectations equilibrium, with a resultant increase in the expected market clearing price. The results in tables 2 and 3 tend to substantiate this result for the multiproduct case, although the perverse outcomes for wheat and maize demonstrate ambiguities that arise in the multiproduct case from the existence of cross-demand effects and negative correlations in yields.

The bottom lines of tables 2 and 3 show the value of social welfare obtained from the two models for different values of ϕ. Welfare is measured using equation (9), that is, using the expected value of the sum of realized or *ex post* producers' and consumers' surplus. This value was obtained directly from the objective function for the revenue expectations model but had to be calculated from the solution to the price expectations model.

These results demonstrate the superiority of market equilibria associated with revenue expectations behavior. For $\phi = 0$, for example, welfare is 270 million pesos greater when farmers plan on the basis of revenue rather than price expectations. Since it can be shown that the social gain accrues entirely to producers (Hazell and Scandizzo 1975), this amount is equivalent to an average gain of about 2,700 pesos (U.S. $200) per farm.

The difference in welfare between the two sets of solutions diminishes as ϕ increases, suggesting that private risk averse behavior on the part of farmers can adequately offset the shortcomings of price expectations behavior. Indeed, when $\phi = 2.0$, the two models have almost identical welfare outcomes.

Various simple measures of the overall goodness of fit between the different price solutions and the base period actuals were used, including the mean absolute deviation and the correlation and the regression coefficients between the model predictions and the base year prices. These indicators all show that the price expectations model provides a superior fit for all values of ϕ, and its superiority increases monotonically with ϕ as measured by the difference between the mean absolute deviation outcomes. Both models provide their best fit when $\phi = 1.0$, a very plausible value given the underlying $E(y) - \phi S(y)$ utility specification.

Base period trade figures correspond closely to both models for ϕ values of 0 or 0.5. However, for $\phi \geq 1.0$ the price expectations model grossly underestimates the level of sugar exports. The revenue expectations model, on the other hand, retains a relatively good fit.

Conclusions

This paper has demonstrated that alternative assumptions about the way in which farmers form

their price and yield expectations have important consequences for the ensuing market equilibrium when production is risky. In particular, while competitive markets are inefficient if farmers ignore correlations between stochastic prices and yields, they are efficient if such correlations are taken into account. The simplest way in which this can be achieved is for producers to project last year's per acre revenue for each enterprise. This approach can be incorporated in agricultural sector models by using the method presented in this paper. As results from an application at a subsector level in Mexico show, the adoption of this method may cause important differences in the solutions as compared with conventional model formulations.

Toward a More Meaningful Measure of Firm Growth

Eddy L. LaDue

Research on the time-related characteristics of the firm has frequently been conducted within the context of growth. Growth is also frequently used by business managers as a measure of success over time. A multitude of measures have been used to chart the rate of growth and in most cases the particular measure used appears to be based as much on expediency as on sound reasoning. For researchers to determine optimum growth strategies, or for firm managers to correctly measure their rate of progress and appropriately evaluate business alternatives, an unambiguous comprehensive measure of growth is required.

Optimum firm organization can be defined in terms of the configuration of assets and processes used at a particular time and optimum growth in terms of changes in the configuration through time. An optimum growth path specifies a preferred firm organization in each time period. However, an optimal firm organization determined for any isolated time period is not necessarily consistent with optimum growth. An appropriate measure of growth must accurately reflect progress over a series of time periods.

As commonly measured, the growth rate can be defined as $g = (E/B)^{1/n} - 1$, where g is compound growth rate, E is size of firm at end of growth period, B is size of firm at beginning of growth period, and n is number of years in the growth period. This definition provides a simple approach to determining average growth rates over time and reduces the problem of measuring growth to a question of the appropriate measure of size. Thus, selection of an unambiguous comprehensive measure of growth requires selection of the appropriate measure of size.

The purpose of this paper is to demonstrate the superiority of an appropriately defined wealth measure of size for use in measuring farm growth. The shortcomings of size measures frequently used are identified. The wealth measure of size and a limited information derivative, profit units, are defined. Finally, the proposed measures are evaluated in an empirical example. The wealth measure proposed should be easily adoptable in research situations where net income is available. For empirical studies where net income information is limited, the profit units measure may be more applicable.

Eddy LaDue is an associate professor in the Department of Agricultural Economics, Cornell University.

Shortcomings of Common Size Measures

Commonly used size measures can be categorized as physical and financial measures of input and output. Indexes of inputs are used by both Renborg and Penrose. Penrose uses total investment exclusively, while Renborg uses a more complete but abstract and less tractable vector of resources. Others have used or suggested use of alternate measures of inputs, such as number of cows and number of acres as the appropriate measure of size.

Although input measures provide an easily understood index of size, particularly for extension clientele, they fail to differentiate productive growth from unproductive growth and do not reflect the difference in productive capacity of alternate assets. An increase in number of cows, number of acres, or total investment does not necessarily imply an improvement in income. Furthermore, if cows are a productive investment, some cows will be more productive than others.

Use of a physical inputs measure of size also excludes the financial characteristics of firm growth. This not only eliminates an important firm characteristic from the measure used but also limits the ability to study the increasingly important influences of financial management on the growth process. For example, when a firm experiences an absolute increase in debts greater than the corresponding increase in assets, the growth rate indicated by physical inputs measure of size exaggerates the rate of progress made by the firm. Changes in a firm's liquidity position and credit reserve are not reflected by physical input measures of size.

Only if one is willing to assume productive homogeneity for all resources at all stages of growth is an input approach to growth measurement appropriate. Such an assumption may be plausible for highly aggregated data but represents a severe handicap for individual-firm research.

Output measures of size such as gross sales or total pounds of milk produced are similar to input measures in failing to differentiate productive growth from unproductive size changes. Gross sales per se also contain a livestock or high-value crop bias, as these items frequently have lower profit margins per dollar of sales or investment than low-value crops. Thus, apparent growth can be achieved through enterprise substitution that may indeed provide little or no real improvement in present or future net income flows. Growth rates may also be confused by

cyclical patterns in commodity prices. Although price trends represent a legitimate influence on growth, purely cyclical changes will tend to either accentuate or offset real growth.

Net worth is a frequently used financial measure of size. Change in net worth reflects the increase or decrease in the firm's value over time, a prevalent farm operator goal. However, changes in equity fail to reflect many changes in assets or liabilities that do not immediately affect net worth. A farm business may show little growth over a ten-year period if an investment near the end of that period generates a large capital loss.[1] Although the farm may be in a markedly improved income-generating position, this is not reflected in the growth rate as measured by net worth.

Desired Characteristics of Size Measures

Recognition of multiple managerial goals has prompted investigations of their effects on optimal growth. Although most of these studies have used some version of linear programming, which requires a single objective function, they have found that varying the objective function does imply different optimal growth strategies. Attempts to reflect multiple goals through the single objective function have required use of arbitrary goal weighting and/or decision rules (Candler and Boehlje; Patrick and Eisgruber). The rudimentary nature of economists' ability to handle multiple goals leads to the conclusion that the size measure used must either represent the most important goal or come closest to representing a compendium of a number of goals.

This paper argues that the present value of net income flows over the relevant time horizon represents the most desirable measure of size. Use of this measure recognizes that farms are businesses and that the primary incentive for operation of a business is income or at least long-run profit maximization. Many other goals are natural derivatives of net income; the real value of net worth is the capitalized value of the net returns it can produce. Although some goals may be inconsistent with growth, use of a net income criterion allows determination of trade-offs between goals in terms that firm managers understand.

The real advantage of an income measure of size is its all-inclusive nature. As indicated above, most size measures exclude some important characteristics of the firm that contribute to determination of firm progress. A desirable measure of size should reflect both intensive and extensive growth. Extensive growth involves changes that increase the quantity of resources used, while intensive growth includes those changes in firm organization and operation that increase productivity or efficiency. It has been argued earlier in this paper that the productivity of resources added during extensive growth must be reflected. A useful size measure for determining growth rates should also reflect the income-generating potential of reallocation of existing resources to more efficient use.

It can be argued that intensive growth is just profit maximization through recombination of existing resources. However, when growth is viewed as a process of change over time that is expected to improve the income position of the firm, efficiency changes (intensive growth) must be viewed as a part of that process. Otherwise, what is called growth represents a result of dynamic processes that may or may not be good for the farm ownership and/or management. When efficiency changes are included, use of net income as a size indicator allows growth to become a measure of good in a dynamic analysis in much the same way that profit is a measure of good in a static analysis.

A Wealth Measure of Size

Incorporation of time horizon with the net income approach implies a total wealth measure of size. For some time, the summation of discounted future income streams into perpetuity has been used as a measure of well-being. Its primary use has been at the theoretical level, and it has not generally been used as a measure of firm size.

Numerous studies (including Barry, Barry and Baker, and Boehlje and White) have used the net present value of some combination of annual net income, consumption, and terminal net worth as the objective function. These studies limit net income and consumption considerations to those achieved within a normally arbitrarily chosen growth period and assume that market or book value of assets held at the end of that growth period accurately represents their income-generating capacity.

In general terms a wealth measure of size can be expressed as

$$w = \sum_{j=1}^{\infty} \frac{X_j}{(1+k)^j},$$

where w is firm size at present, X_j is after tax net income for time period j, and k is after tax cost of equity capital.

After tax net income in this case is the net income that the firm would expect if it was operated at its present size (no further growth) in the future; that is, size is indicated by the present value of the income that would be generated if the business were static and operated without organizational change into perpetuity. This assumes that the factors affecting relative real income will remain constant over time and that the debt position remains constant. In most

[1] Farm machinery, specialized buildings, and the family car all frequently sustain capital loss. If one tries to sell them the day after they are purchased, the market value is significantly less than the purchase price or construction cost. This fundamental fact is often not recognized in theoretical analyses, which show that net worth maximization is consistent with profit maximization.

cases, the best estimate of this expected income is indicated by recent income experience. Under deterministic static conditions, one year of data would be sufficient. Under highly variable conditions, a longer time period would be required.

After tax net income for any period of business operation can be calculated as cash income minus cash operating expenses, interest on debt, taxes, and cost of capital maintenance. Cost of capital maintenance is similar in concept to depreciation, except that it has no direct tax implications. It represents the annual capital investment required to maintain the present earnings stream of the business over an extended time period. Actual depreciation amounts from farm business records may be usable in cases where selected useful lives are realistic in terms of the physical asset durability.

Operationally, use of a wealth measure of size requires use of a shorter time period than infinity. The appropriate time horizon depends upon the type of agriculture being studied and other factors. Periods of twenty to thirty years have often been used in growth research. Using the farming horizon of a potential purchaser of the business appears most defendable. Since the primary first-year decision of a potential purchaser is whether to buy the farm, use of the farming horizon is consistent with Boussard's suggestion that the appropriate planning horizon is the time period within which it is necessary to plan in order to make first-period decisions. The value of an operating farm business is the present value of the income stream that a young man could expect to derive from it during his lifetime.

The only modification of the wealth equation required to allow use of a finite investment horizon is inclusion of the terminal value of assets. When discounted back from infinity, the terminal value of assets is zero and can be ignored. With a shorter period, the value of these assets becomes a potentially important contribution to wealth. The new wealth measure of size becomes

$$w = \sum_{j=1}^{n} \frac{X_j}{(1+k)^j} + \frac{A}{(1+k)^n},$$

where n is number of years in discount time period, and A is total firm asset value minus total firm debts (net worth).

When the firm is assumed to be operating under static, no-growth conditions during the entire time period, the terminal value of the assets is equal to their value at the time size is being measured, barring any relative real price changes in asset values. Within the present economic environment, there appears to be little real basis for sustained price changes in any asset group except land. Prices of other assets will likely fluctuate with production and construction costs, but there is no a priori reason to expect change in real value. Alternately, population pressures on available land may provide continued appreciation in land value. Recognition of this factor requires use of a terminal land value that accounts for the appreciation that is expected.

The wealth equation modified to include land appreciation becomes

$$w = \sum_{j=1}^{n} \frac{X_j}{(1+k)^j} + \frac{(A-L) + L(1+a)^n}{(1+k)^n},$$

where L is land value at time size is measured, and a is land appreciation rate. As measured in this manner, present wealth of the farmer as a measure of size accounts for the profitability and efficiency of the firm through net income, the capital structure through interest payments included in the net income calculations and land appreciation plus income beyond the potential planning horizon through the discounted terminal value of assets. Using wealth as the measure of size at the beginning, end, and any selected interim point of the growth period will accurately measure the growth that has occurred.

Profit Units—A Limited Requirements Approach

The primary limitation of the wealth measure of size is that the entire income situation of the firm must be known. Although this may be possible for many cases, it is less appropriate for empirical studies where data on large numbers of actual farm businesses are involved. A measure of size, which is more limited in its data requirements but yet allows maintenance of the net income concept, is profit units. Profit units are essentially an indication of the profit potential of the firm. Each profit unit represents $1 of sustainable estimated profit.

Operationally, this requires determination of the expected profit for each enterprise based on a set of physical criteria that can be used to indicate the likely income potential of the enterprise. Research reports and extension accounting project data provide sources of information from which profit potential of individual enterprises can be estimated. Budgeting of typical farm situations may also provide the required information. The profit units tables for dairy cows, corn silage, and hay in New York for 1971 are shown in tables 1 and 2. Dairy enterprise

Table 1. Profit Units per Cow, 1971

Milk Sold per Cow (Lbs.)	Housing System Type: Stanchion, Under 50 Cows	Stanchion, 50 Cows and Over	Free Stall, Under 100 Cows	Free Stall, 100 Cows and Over
Less than 10,000	—50	—60	—20	0
10,000–11,999	0	0	20	40
12,000–13,999	30	40	50	80
14,000 and over	50	60	90	120

Table 2. Profit Units per Acre for Hay Crop and Corn Silage, 1971

Yield (Tons per Acre)	Acres of Crop		
	Less Than 50	50–99	100 and Over
Hay crop			
Less than 2.0	−15	−5	0
2.0–2.9	0	5	10
3.0 and over	5	10	15
Corn silage			
Less than 12.0	−40	−25	−20
12.0–15.9	−20	−5	0
16 and over	0	15	20

profit units are a function of production level, size of herd, and housing type. Determination of profit units per firm requires summation of the total profit units for all firm enterprises.

Profit, as used in this context, is equal to return on capital and management. The lack of financial data eliminates any consideration of the debt level, and thus the distribution to all capital is included in the residual profit. If financial information were available, it would be possible to specify the debt level, or assume an average equity ratio, and reduce profit to a return to management.

As a measure of size, profit units allow segregation of profitable and unprofitable growth. They are also an immediate reflector of organizational changes designed to improve income. Their primary advantage is the limited individual firm data required for their implementation. They provide some standardization of farms by excluding certain individual firm or manager peculiarities and allowing isolation of general relationships in firm growth that could be hidden by measures more sensitive to specific farm situations. Cyclical price patterns may also be eliminated, which would be particularly useful when different kinds of businesses are being compared.

In addition to their inability to reflect the capital ownership structure of the firm, profit units have the disadvantage of requiring their delineation per unit of each enterprise based on physical data. Although the physical data are easier to observe or generate, the relationships between these factors and expected profit are often not fully known. The profit units measure assumes that the physical data-profit relationships used in developing the profit units tables represent the actual situation for all farms. Thus, the soundness of profit units as a measure of size will be a direct derivative of the accuracy of the physical data-profit relationships used.

Although profit units are obviously a less comprehensive measure than the wealth approach from which they are derived, they maintain the desirable property of including both intensive and extensive growth. The limited data required make profit units particularly applicable for empirical growth studies.

An Illustration

To illustrate certain characteristics of selected size measures, data for a typical northeastern dairy farm were developed indicating alternate sets of operating and financial results of the type that are frequently observed during the growth process (table 3). A 40-cow firm that doubles its herd size over the growth period by duplicating the initial resource base to achieve an exact doubling of resources, receipts, and net income is used as a base for comparison. The other firm growth situations include a doubling of herd size with (*a*) an increase in productivity of animals and land, (*b*) an investment near the end of the growth period that involves a capital loss (expenditures for construction exceeded market value of structure constructed), (*c*) a doubling of all operating data but an increase in the proportion of debt capital, and (*d*) an increase in operating cost rates, possibly reflecting poor management.

Rates of growth for each alternative as indicated by various measures of size were calculated (table 4). For ease in exposition, rates of growth are presented as a percentage of total growth over the period rather than compound annual rates. The benchmark change of doubling business size indicates the expected 100% change for all measures except total cash costs and profit units. The labor supplied by the operator for the first 40 cows must be hired for the added animals, and total cash costs increase more than twofold, although total resources used have exactly doubled. Profit units indicate a larger than 100% increase because they assume that the increased per unit profit normally attendant with the indicated change in herd size (table 1) is achieved.

Most trained observers would agree that doubling size of business and increasing crop and animal productivity or building modern housing structures indicate greater "growth" in the business than doubling herd size alone. Alternatively, they would also agree that doubling herd size while more than doubling outstanding debt or expenses indicates a less improved situation than an exact doubling of all factors. Given this rough ranking of alternatives, one can evaluate the various measures of size. Any violation of this ranking can be taken to indicate failure of a measure to accurately reflect growth.

The resource use measures of size either totally fail to differentiate among the situations indicated or give incorrect indications of appropriate ranking of alternatives. Herd size provides no differentiation. Total investment indicates more growth when new housing facilities are constructed but fails to differentiate among all other alternatives. Total cost does indicate differences among alternatives but rates a doubling of herd with excessive costs above a similar change with controlled costs.

Output measures also fail to differentiate among alternatives. Gross receipts indicate no differences between the alternatives except for a higher rate of growth with increased productivity. The capital loss characteristic of the building alternative causes net

Table 3. Business Evaluation Criteria for Alternative Growth Achievements, Northeast Dairy Farm, Simulated Data

Business Factor	Before Growth	Doubling Business Size	Doubling Business Size Plus: Productivity Increases	Doubling Business Size Plus: Building-Capital Loss[c]	Doubling Business Size Plus: Increased Debt Capital	Doubling Business Size Plus: Excessive Cost Increases
Cows (no.)	40	80	80	80	80	80
Acres of corn	35	70	70	70	70	70
Acres of hay	100	200	200	200	200	200
Total investment ($)	100,000	200,000	200,000	230,000	200,000	200,000
Milk/cow (lbs.)	13,000	13,000	14,000	13,000	13,000	13,000

worth to severely discount the growth achieved for that alternative. Instead of indicating greater growth than with a mere doubling of resources, it indicates less. In fact, net worth rates the alternative with increased debt capital as representing a change similar to construction of new facilities. Net worth is unable to differentiate among the other alternatives.

The ability of profit units to measure the various characteristics related to size depends upon the variables included in the functional relationships developed for determining profit units for each enterprise. Productivity increases and improvement in housing facilities were recognized and properly evaluated (at least in terms of direction of effect). Profit units did not discern the effects of capital structure changes or cost increases. Only the wealth measure was able to appropriately discern those changes that implied a more than doubling of size from those that implied less. Although the alternatives considered here include only one farm type, the wealth measure is well adapted to analysis across different farm types. Size is not tied to any enterprise specific statistic but uses asset, income, and expense items common to all farm types.

Although this illustration has tested only the ability of these size measures to rank alternatives as better or worse than a standard, only the wealth measure stands up under this weak evaluation criterion. An evaluation of the size measures' ability to appropriately indicate relative magnitudes of growth would also be useful. However, such an analysis is difficult to conduct in the absence of a standard

Table 4. Growth Rates Indicated by Alternate Size Criteria, Northeast Dairy Farm, Simulated Data

Size Measures	After Growth With: Doubling Business Size	Productivity Increases	Building-Capital Loss	Increased Debt Capital	Excessive Cost Increases
Number of cows	100	100	100	100	100
Total investment	100	100	130	100	100
Total cash costs	133	183	100	133	144
Gross receipts	100	126	100	100	100
Net worth	100	100	40	50	100

Wealth[a]	100	140	174	10	1

[a] Thirty-year investment horizon, zero land appreciation, and 7% after tax cost of equity capital were assumed.

against which the evaluation can be made. If a perfect measure of growth existed, one would be able to evaluate other measures, and the question of an appropriate measure would be easily solved. While striving for that perfect measure, one should at least use only measures that give appropriate ranking for important observable alternatives.

Summary

Assuming growth research is an appropriate vehicle for study of dynamic processes of the farm firm, an appropriate measure of growth is necessary. The problem of selecting the correct measure of growth can be reduced to a search for an appropriate measure of size. Many of the measures frequently used fail to differentiate between productive and unproductive growth and become inoperable as determinants of optimum growth rates. This demonstrates the need for a size measure that can evaluate and net out firm changes that imply an improvement in the owner-operator income position and those that imply deterioration.

Two measures are proposed that might meet these criteria: wealth and profit units. Profit units have the advantage that the necessary firm data are easier to obtain, some standardization of individual firm data is achieved, and the net income concept is maintained. The wealth measure incorporates projected net income and net worth through discounting. By using net income, it captures all the factors that influence the achieved wealth position of the firm and in essence incorporates most of the other measures of size. It does require complete business and financial data but, as illustrated by example, is superior to commonly used measures in its ability to rank alternative growth situations.

Another Look at the Hog-Corn Ratio

Karl D. Meilke

The hog-corn price ratio has long been used as a proxy for profits in the pork sector. This statement remains true even though Blosser pointed out a decade ago that the hog-corn price ratio is deficient on at least two grounds: corn is not as important an input in producing hogs as it once was and the same price ratio implies different levels of profitability depending on the level of corn and hog prices.[1] Why has the hog-corn ratio remained a widely used measure of profitability? Part of the answer can be found in the simplicity of the ratio. In addition, the stability of corn (feed) prices over much of the past twenty years meant that the price ratio moved directly with hog prices and that an increase in the ratio implied an increase in profitability. Thus, notwithstanding Blosser's concerns about the relative decline of corn as an input, the hog-corn price ratio apparently was an excellent measure of profitability. During 1970–75, corn prices were more volatile and higher (table 1) than in previous years, suggesting the hypothesis that the hog-corn price ratio would be less useful as a predictor of hog supply since the correlation between hog prices and profitability declines as corn prices become more variable.[2] In addition, the greater variability may provide more precise estimates of the separate supply inducing effects of corn and hog prices.

This note has two objectives: to determine the supply response of U.S. pork producers to changing hog and feed prices over time and to determine if the hog-corn price ratio is an adequate predictor of hog supply when the prices of both hogs and feed are volatile. A polynomial distributed lag model of quarterly U.S. hog supply response is estimated for two different time periods, 1960–69 and 1970–75. For each time period, two equations are estimated, one using the hog-corn price ratio as an explanatory variable (equation (1)) and a second using hog and feed prices as separate explanatory variables (equation (3)).

Table 1. Coefficients of Variation for Hog Price, Feed Price, and the Hog-Corn Price Ratio

	Coefficient of Variation	
Variable	1960–69	1970–75
Hog price	0.19	0.35
Feed price	0.09	0.39
Hog-corn price ratio	0.17	0.27

The general form of the estimated equations are

$$(1)\quad QS_t = \alpha_1 D_1 + \alpha_2 D_2 + \alpha_3 D_3 + \alpha_4 D_4 + \alpha_5 T + \sum_{i=0}^{13} \beta(i)(PH/PC)_{t-i} + \epsilon_{1t},$$

where

$$(2)\qquad \beta(i) = \gamma_1 + \gamma_2(i) + \gamma_3(i)^2,$$

and

$$(3)\quad QS_t = \phi_1 D_1 + \phi_2 D_2 + \phi_3 D_3 + \phi_4 D_4 + \phi_5 T + \sum_{i=0}^{13} \delta(i) PH_{t-i} + \sum_{i=1}^{13} \theta(i) PF_{t-i} + \epsilon_{2t},$$

where

$$(4)\qquad \delta(i) = \lambda_1 + \lambda_2(i) + \lambda_3(i^2)$$

and

$$(5)\qquad \theta(i) = \mu_1 + \mu_2(i) + \mu_3(i^2),$$

and QS is commercial pork production (million pounds), PH is the average price of barrows and gilts at seven markets (dollars per hundred weight), PC is the average price received by farmers for corn (dollars per bushel), PF is 0.88 times the price of corn (dollars per ton), plus 0.12 times the price of 44% protein soybean meal at Decatur (dollars per ton), T is a time trend, and D_1, D_2, D_3, and D_4 are seasonal zero-one variables.[3]

Karl Meilke is an assistant professor in the School of Agricultural Economics and Extension Education, University of Guelph, Canada.

The author acknowledges helpful comments by the *Journal* reviewers. This project was funded in part by the Ontario Ministry of Agriculture and Food.

[1] According to the *Livestock and Meat Situation* (USDA), corn accounts for approximately 51% and feed, 73% of the costs, excluding the feeder pig, of a Corn Belt hog-feeding operation. Several experiments were conducted to see if a hog-feed price ratio would predict better than a hog-corn price ratio, but in general there was little difference between the two variables. Nevertheless, when the two variables are separated, feed costs are used instead of the price of corn, accounting for the cost of soybean meal in pork production. No attempt was made to include nonfeed costs in the analysis.

[2] A reviewer has pointed out, and correctly so, that at current corn prices corn is not only an input into the pork production process but also a substitute for pork production. This is another reason why the hog-corn price ratio is less useful as a predictor now than previously.

[3] The Statistical Reporting Service considers the prices received by farmers and the prices paid by farmers to be the same.

Equations (2), (4) and (5) indicate that the weights assigned to past prices are represented by second-degree polynomial adjustment equations with a lag length of thirteen quarters. All but zero-one variables are converted to logarithms so the coefficients are elasticity estimates. The degree of the polynomial and the length of the lag were chosen following the procedure outlined by Meilke. Readers unfamiliar with polynomial distributed lags are referred to Chen, Courtney, and Schmitz; Kmenta, pp. 492–95; and Meilke.

The supply response functions contain the current price, so supply is determined simultaneously with demand. The equations are estimated using ordinary least squares for the reasons stated by Heien (p. 312). The results of estimating equations (1) and (3) for 1960–69 are given in table 2 and identified as equations (1a) and (3a). Both equations explain more than 90% of the variation in hog supply over the estimation period. This finding supports the argument that the hog-corn price ratio provides a good explanation of hog supply when the price of corn is relatively constant. The long-run elasticities from equation (3a) show that hog supply is more responsive to a 1% change in feed prices than in hog prices, given their respective elasticities of −0.56 and 0.36.[4]

Table 3 contains the parameter estimates for equations (1) and (3) in 1970–75. Contrary to the earlier time period, equation (1b) explains only 67% of the variation in hog supply compared with 98% by equation (3b). In addition, most of the coefficient estimates in equation (1b) have small *t*-ratios, while in equation (3b) they are much larger. The high degree of serial correlation in equation (1b) is also a good indication of misspecification, especially given that equation (3b) eliminates the serial correlation.[5]

In comparing equation (3) between the two time periods, three factors seem worthy of mention. First, the response of hog supply to changes in the price of hogs and feed is more rapid in the later time period with estimated mean lags of 7.22 and 5.78, respectively, compared with 10.67 and 8.50 in the earlier time period. Second, the elasticities of supply response with respect to both hog and feed prices are over three times as large in 1970–75 compared with 1960–69. Finally, the long-run feed price elasticity (−2.04) in 1970–75 tends to be slightly larger than the hog price elasticity (1.65) just as in the earlier time period.[6]

[4] Long-run elasticity is the sum of the regression coefficients on the price parameters.

[5] Serial correlation can of course be eliminated from equation (1b) using standard econometric techniques, but when serial correlation is due to misspecification it is surely better to correct for it by removing the specification error.

[6] All four of the equations estimated provide some empirical

Although equation (3b) fits the historical time series better than equation (1b), this does not guarantee equations (3a) and (3b) will give better predictions than equations (1a) and (1b). To test this hypothesis, two prediction interval tests were conducted. The first reported in table 4 compares the performance of equations (1a) and (3a) in predicting hog supply from 1970(1) through 1976(2). The results indicate equation (3a) gave a mean absolute percentage error of 4% compared with 12% for equation (1a).[7] Similarly, the maximum single quarter error was 12% with equation (3a) and 32% with equation (1a).

The second prediction interval test consisted of using equations (1b) and (3b) to predict hog supply from 1976(1) through 1977(1) (table 5). Actual supplies are known only for the first two quarters. Consequently, the supplies reported for the last three quarters are the U.S. Department of Agriculture forecasts. USDA hog price forecasts plus futures market grain prices were utilized in predicting hog supply the last three quarters. The maximum difference between the USDA forecasts and the forecasts using equation (3b) is 5% in 1976(4) compared with an 18% differential in 1977(1) using equation (1b).

In conclusion, the above analysis supports the hypothesis that the hog-corn price ratio may provide a good explanation of hog supply when corn prices are constant but not when they are fluctuating. Consequently, forecasters and market analysts should consider the independent impacts of changing hog and feed prices on hog supply and not limit themselves to considering only the hog-corn price ratio.

[*Received July 1976; revision accepted October 1976.*]

Table 4. Results of Using Equations (1a) and (3a) to Predict Hog Supply from 1970(1) through 1976(2)

The Storage of Potatoes and the Maine Potatoes Futures Market

Benjamin Sexauer

The relationship between the storage of potatoes and the carrying charges reflected on the futures market for Maine potatoes gives rise to a situation in which the observed facts do not seem to agree with the accepted theory. The theory regarding intertemporal price relationships based on the work of Brennan, Telser, and Working establishes that the difference between the current price and the expected price of a storable commodity must be equal to the marginal cost of storage minus the convenience yield. The relationship between the amount of a commodity held in storage and the equality of the marginal cost of storage with the temporal price spread gives rise to a supply of storage curve. As estimated by Brennan, Telser, and Working, this supply of storage curve slopes upward to the right. More storage will be supplied at a high return per unit and less storage at a low return per unit stored.

The carrying charges reflected on the Maine potatoes futures market seemingly contradict the theory of the price of storage in two respects. First, the spreads between futures, which establish a return to storage, sometimes appear to greatly exceed any typically plausible cost of storage. On 1 March 1976, the March future for Maine potatoes sold for $8.35 per hundredweight, whereas the May future was selling for $12.63 per hundredweight. The return to storing potatoes for two months was $4.28 per hundredweight. Second, the relationship between the level of potato stocks and the carrying charge appears to be the opposite of that previously estimated for commodities with continuous inventories. For potatoes, the seasonal pattern associates large stocks with a narrow carrying charge and small stocks with a wide carrying charge. The level of potato inventories and the spread on the futures market produce a relationship that slopes downward to the right.

The fall potato crop accounts for over 75% of annual U.S. production and in recent years has been about 84% of the total. Fall crop potatoes are stored for consumption over a seven- or eight-month period. However, potatoes cannot be effectively stored for a whole year, since they are semiperishable. Potatoes, therefore, give rise to a discontinuous inventory situation. The task of intertemporal allocation is more difficult for a discontinuous inventory commodity. Potato prices must be established during the storage season with the objective of exhausting the supply of potatoes in storage coincidently with the availability of spring and early summer potatoes (Gray). Potato storage is conducted not by merchandising or storage specialists but primarily by growers. The primary requirements of a potato storage facility are adequate insulation, ventilation, and heating and the means to enter and remove the tubers efficiently.

Benjamin Sexauer is an assistant professor in the Department of Agricultural and Applied Economics, University of Minnesota.

The author wishes to acknowledge the helpful comments of Martin Abel, Roger Gray, James Houck, Edward Johnston, Anne Peck, Neil Pelsue, Terry Roe, Duane Smith, Abraham Subotnik, and the anonymous reviewers of this manuscript.

The Supply of Storage Relationship

The basic supply of storage relationship is $(P_t^{t+1} - P_t) = f(S_t)$, where P_t is price in period t, P_t^{t+1} is, in period t, the price expected to exist in period $t + 1$, and S_t is the inventory of the commodity. The important characteristics of the conventional supply of storage curve are the wide, basically horizontal segment in the middle, the steep upward slope when storage capacity is reached, and the negative price of storage section, which exists because of a convenience yield derived from inventory holding (Working, p. 1259).

In a rigorous development of this theory, Brennan conceived of a demand for storage and a supply of storage curve, which achieve equilibrium when the net marginal cost of storage equals the expected change in price. With a futures market, the expected price change is the relevant spread. The supply of storage curve is identified in a statistical sense because it remains basically stable, while the demand for storage curve shifts between seasons and within a season (Brennan, p. 57). The supply curves, estimated for a number of commodities, closely approximate the shape of the idealized supply of storage function. However, these supply of storage functions were estimated for highly storable, continuous inventory commodities such as the major grains. Brennan did examine the storage relationship for cheese, butter, and shell eggs, but these products, although perishable, are continually, not seasonally, produced.

In figure 1, the level of Maine potato stocks has been plotted with the relevant monthly carrying charge or return to storage reflected on the Maine potato futures market.[1] The monthly spread is be-

[1] The stock reports of the U.S. Department of Agriculture are defined as total stocks held by growers, local dealers, and

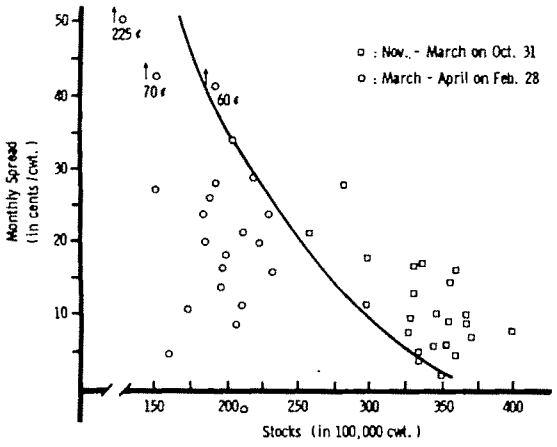

Figure 1. The relationship between the spread on the futures market and the level of potato stocks

tween the near future and the next future contract divided by the number of intervening months. In figure 1, the 1 March stock figures are aligned with the March to April spread on the last trading day in February for crop years 1954–74 (twenty-one observations), and the November stock levels with the November to March spread on the last trading day in October for 1952–74 (twenty-three observations).[2]

High stock levels in figure 1 are associated with a low carrying charge and low stocks with a high carrying charge, the reverse of the normal price of storage relationship. Also, there is no inverse charge; the carrying charge is always positive with one exception. The strong seasonal pattern is explained in the next section. Regression analysis of the data presented in figure 1 using ordinary least squares and an inverse functional form yields the following results:[3]

$$(1)\quad (P_t^{t+1} - P_t)/h = \underset{(3.04)}{-41.76} + \underset{(4.81)}{15{,}458}(1/S_t),$$

$$R^2 = 0.36,$$

where $(P_t^{t+1} - P_t)/h$ is the monthly carrying charge, the spread divided by the number of months h until the delivery month, and S_t is stocks of Maine fall crop potatoes. When equation (1) is plotted on figure 1, the problem is clearly revealed. The slope of equation (1) is negative, the opposite of the normal upward sloping supply of storage curve. In addition, the relationship between the monthly carrying charge and stocks is not a strong one. However, stocks are an important variable as reflected by the t-statistic.

The Costs of Potato Storage

The explanation for this pattern can be found in the influence that the potato's biological characteristics and its storage situation have on the costs of storage. The price of storage for potatoes is not primarily a function of the level of stocks, as Working's price of storage theory postulates. Potato storage is significantly more complex than storing grains. Potatoes are a tuber, a rather delicate living organism, which respires, loses weight, sprouts, and is subject to diseases and rotting. Because of the potato's perishability, the costs of storage are influenced by the length of the storage period, the price level, and the storage characteristics of the tubers.

Figure 2 quantifies as accurately as possible the costs of storing potatoes over the course of the storage season. The horizontal axis represents a temporal not a quantity measure. Figure 2 is based partially on cost estimates derived by Sparks. Although his studies apply to Russet Burbank potatoes in Idaho, the orders of magnitude, if not the exact values, should still be fairly applicable to the storage situation in Maine. The average fixed cost curve covers the investment costs of the storage facility including interest, taxes, insurance, and depreciation (Sparks, pp. 90–91).

The average basic costs curve includes the fixed costs, the costs of operation and maintenance, handling, and antisprout material, plus the costs associated with weight loss. Based on Sparks' figures and those from other studies, during a storage of six months a weight loss of some 5.61% to 6.65% can be

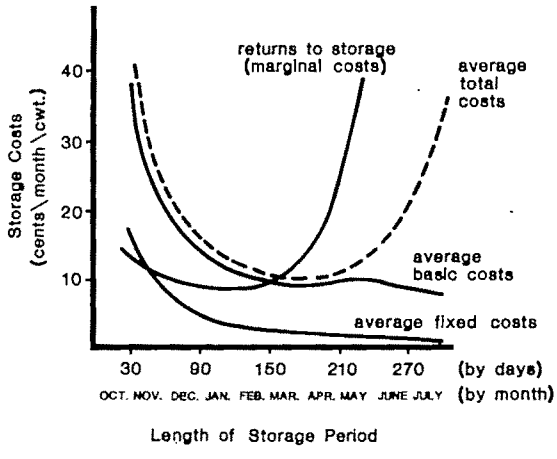

Figure 2. The pattern of storage costs over the storage season

processors and are equal to production minus disappearance (USDA 1952–69 annual, 1956, 1961, 1967, 1972; Pelsue and Kalaw).

[2] The stock reports for the first of the month are not issued until several days later. By using the spread on the last trading day of the preceding month, the assumption is made that the market accurately predicts the stock report before its issuance. Since a stock report is not issued on 1 November, this figure was computed based on the production figure, 1 December stocks, and the relation of total shipments through the end of October and through the end of November.

[3] The t-statistics are given in parentheses.

expected (Smith, p. 351; Sparks and Summers, p. 14). In addition, the monthly rate of weight loss is highest at the beginning and toward the end of the storage season. The cost is obtained by multiplying the percentage losses by the value of the potatoes. A price of $3.00 per hundredweight was assumed for figure 2. Even counting the cost of weight loss, average basic costs are a decreasing function of the length of the storage.

However, the tabulation of costs summarized in the average basic costs curve is incomplete. Potatoes undergo quality deterioration other than simple weight loss. The cost due to grade defects and quality change are also dependent on the price level and the length of storage. The average total cost curve adds the costs associated with quality change at a $3.00 per hundredweight price level to the average basic costs. This curve is drawn as a dashed line to indicate its hypothetical nature, but its measurement is based on a careful appraisal of potato storage. This distinction was made between a basic costs curve and a total costs curve due to the accuracy of the underlying cost estimates of the former and the less reliable inferences about some of the deterioration cost components of the latter.

The average total cost curve lies only slightly above the basic costs curve during the first part of the storage season when losses to quality change are low. However, deterioration losses are not a simple linear function of the length of the storage. Toward the end of the storage season, quality change losses begin to increase sharply as the tubers break dormancy and the outside temperature begins to rise and fluctuate. The percentage of monthly shipments of Maine tablestock potatoes with no sprouting has averaged over 99% through January for crop years 1966–73. The figure becomes 95% for February, 92% for March, 85% for April, 81% for May, and only 62% for June (Johnston and Pelsue, p. 27). Because of the potato tuber's ultimate perishability, storage losses would reach 100% at some point in the summer. The average total cost curve in figure 2 assumes that quality change losses would reach 100% sometime in July.

In addition, since potato storage is primarily by the grower, joint production considerations tend to increase the upward slope of the average total cost curve in the late spring. The potato producer-storer is engaged in two businesses, production and storage. Planting usually begins in Maine from 10 May to 15 May. The bulk of the Maine potato production is by small growers who simply do not have the capacity to be planting and moving potatoes out of storage at the same time. Planting must be given priority. Those growers that do store into May will probably be the larger outfits. They will require two crews, one for planting and one for potato handling. Therefore, the costs may be higher.

If all the relevant factors are taken into account, monthly potato storage costs have a U-shaped pattern over the storage season reflected in the average total cost curve in figure 2. The average total storage cost curve would shift upward for high priced potatoes and downward for low priced potatoes. The curve would also be affected by the storability of the crop. Although there is no simple physical measurement of this factor, tubers at harvest do vary from year to year in how well they will store. Weather conditions in the fall such as excessive cold or moisture and certain diseases produce tubers that have poor storage properties. For example, a frost in 1975 and heavy rains in 1972 prior to harvest gave rise to unusually severe storage problems.

Finally, the returns to storage curve in figure 2 describes the normal pattern of the carrying charge reflected on the futures market over the storage season. The return to storage has averaged 10.67¢ per month for November–March, 9.42¢ per month for January–March, and 32.81¢ per month for March–April for the years covered by this study. The carrying charge is normally somewhat lower on 31 December than on 31 October and rises sharply by 28 February. The return to storage curve would, in fact, approximately coincide with the temporal marginal cost curve if it were drawn in figure 2. As a general pattern, the carrying charges reflected on the futures market are equal to the cost of holding a unit of potatoes one more unit of time. However, the cost of storage and hence the return to storage are a function of the period in the storage season, the price level, and the storability of the crop, which shift the cost curves. The spread observed on 1 March 1976 could, therefore, accurately reflect the marginal cost of storing potatoes because of the very high price of $8.35 per hundredweight and the low storability of the 1975 crop due to frost damage.

The Carrying Charge Relationship for Potatoes

Previous analyses have assumed a stable supply of storage curve that was identified by the shifting demand for storage curve. However, for a seasonally produced, semiperishable commodity, the supply function is also shifting significantly over time. The storage cost per unit of inventory and the supply of storage curve shift as a function of the price level, the length of storage, and the storability of the crop. The supply of storage function for potatoes is not statistically identifiable in the normal single equation approach, which Brennan, Telser, and Working utilized. Therefore, the observed negative relationship between the carrying charge and the stock level should not be interpreted as a downward sloping supply of storage curve. A significant identification problem gives rise to the observed downward sloping carrying charge-stocks relationship for potatoes. The situation requires the simultaneous estimation of both the demand and supply schedule.

The demand for storage derives from the demand for consumption of the commodity. The change in price between the next period and the current period

$(P_{t+1} - P_t)$ is determined by consumption in the two periods. Consumption in a period is equal to the stocks carried into the period plus production minus stocks carried out of the period. In the demand for storage schedule, the price difference $(P_{t+1} - P_t)$ was specified by Brennan as a function of current stocks (S_t), stocks next period (S_{t+1}), and last period (S_{t-1}), current production (X_t), and production next period (X_{t+1}) (Brennan, pp. 51–52; Telser, pp. 234–35). This relationship is an *ex post* one, since P_{t+1}, S_{t+1}, and X_{t+1} are not known until next period. However, what is of interest is the perspective on the demand for storage in the current period. Therefore, this function should really be specified as an anticipated demand for storage with the difference between expected price and the current price $(P_t^{t+1} - P_t)$ being a function of the above factors, except that expected stocks (S_t^{t+1}) replaces S_{t+1} and expected production (X_t^{t+1}) replaces X_{t+1}. This demand curve should have a negative slope with respect to S_t.

Based on the storage characteristics of potatoes, the supply of storage function should be extended to include the price level, the length of the storage, and the storability of the crop as exogeneous variables. Observations on storability are not available, though. Estimation of the demand and supply schedule yield the following results:

$$(2)\quad (P_t^{t+1} - P_t)/h = \underset{}{15.17} - \underset{(0.30)}{18.94}S_t + \underset{(5.56)}{3.79}S_{t+1} + \underset{(5.47)}{15.92}S_{t-1} + \underset{(5.34)}{4.06}X_t - \underset{(5.57)}{3.34}X_{t+1} + \underset{(6.06)}{}$$

and

$$(3)\quad (P_t^{t+1} - P_t)/h = \underset{}{-23.07} - \underset{(0.48)}{0.0033}S_t + \underset{(0.26)}{0.0168}P_t + \underset{(6.79)}{7.56}D_t. \underset{(0.40)}{}$$

The dependent variable and S_t are specified as in equation (1), and D_t is a seasonal dummy variable: 0 for the November–March period and 1 for the March–April period; P_t is the price level of the near future; S_{t+1} is 1 March stocks for the November–March period and 1 April stocks for the March–April period; S_{t-1} is Maine fall production for the November–March period and 1 February stocks for the March–April period; X_t is winter crop production for the November–March period and early spring production for the March–April period, and X_{t+1} is early spring production for the November–March period and late spring production for the March–April period.[4] Both X_t and X_{t+1} apply to U.S. production, and S_{t+1} and X_{t+1} are substituted as proxies for S_t^{t+1} and X_t^{t+1}, since these expected levels are not observable.

Equations (2) and (3) were estimated by two-stage least squares to obtain consistent estimates of the coefficients, treating S_t as an endogenous variable. The functional form is linear. In equation (2), the demand for storage curve, the signs of the coefficients are as predicted by Brennan. However, in equation (3), the supply curve, neither the coefficient on stocks or the seasonal dummy variable are statistically significant.

There are two primary explanations for the disappointing estimates of the supply of storage function.[5] First is the necessary omission of storability as a variable. With storability omitted, the shifts in the supply curve are not accounted for adequately. Second, the supply function may not be statistically identified. Although the demand and supply schedules in their conceptual specification are both identified, the demand equation may not contain an adequate number of sufficiently exogenous variables to allow for the estimation of the supply function. In fact, variables considered exogenous in both equations such as S_{t+1}, S_{t-1}, and P_t may actually be endogenous to a fuller conceptualization of the system; hence, the demand function may also not be truly identified.

Conclusions

For the commodities previously studied, the cost of storage was primarily a function of the inventory level, and the observed carrying charge-stocks relationship was the supply of storage schedule. The demand function could not be statistically identified under those circumstances, though. For a discontinuous inventory, semiperishable commodity like potatoes, the price level, the length of storage, and the storability of the crop influence the cost of storage. Since both the demand and supply schedule are shifting, the observed downward sloping carrying charge-stocks relationship identifies neither schedule. In this analysis, the demand for storage function for potatoes has been estimated, but the supply schedule could not. For potatoes, the shifts in the supply schedule are substantial enough to trace out the demand schedule. Further work is suggested in estimating more precisely and completely the costs of storage and the supply of storage function as part of a more complete system. In addition, a means of measuring and the collection of data on the storability factor are needed.

[*Received October 1975; revision accepted September 1976.*]

[4] An 1 April stock figure is only available since 1972. April stocks were estimated by subtracting March shipments from the 1 March stocks minus a 10% correction factor. The 10% correction factor was determined on the basis of the three years for which April stock data are available.

[5] In addition, a multicollinearity problem exists in equation (3), since the correlation between S_t and D_t, the seasonal dummy, is − 0.93. The November–March and March–April periods were, therefore, analyzed separately. However, this approach did not improve the estimates.

Simulation of Agricultural Policy Formation as a Teaching Approach

Fred C. White

Policy formation can best be described as problem solving. Policies are formulated so that they appeal to a sufficient number of involved parties to accept the policy as an improvement over the present situation (Bauer). Understanding the environment and operation of this political process helps students formulate critical judgments concerning important economic policy issues. Because this process is so complex, it warrants special attention by educators. Agricultural policy instruction, in particular, has an opportunity to make economic abstractions meaningful and to get students involved in the learning process by analyzing relevant policy issues. Students can actively participate in a policy formulation learning process through role-playing simulation in which they represent people involved in real-world situations and make decisions based on available information. Such simulation helps students understand the policy-making process and the relationship between policy making and its results. This paper describes role playing simulation in agricultural policy classes.

Simulation and Gaming

One way to increase a student's ability to apply economic theory in a policy situation is to cast him in the role of economist and policy maker. In simulation, students participate in a decision-making experience within a controlled environment. The complexities of a real-world process are simplified, and certain representative features can be easily understood and readily manipulated (Taylor). By directly involving the student, he understands because of his own experience, observations, and analysis. The student is able to move from abstraction to reality after interpreting his behavior and analyzing the results (Joseph).

Simulation benefits the student in several ways. Students are exposed to a variety of viewpoints and a range of outcomes related to particular situations (Taylor). This process helps students understand the perspectives of individuals whose viewpoints differ substantially from their own. They can act on more decisions than in real life, and the results of the decisions are immediately revealed. With the results known, decisions can be evaluated through individual review or group discussion.

For almost a decade, agricultural economists have been interested in using simulation to teach university students. During this period, instructional simulation has been applied to several areas (Kendrick). One of the most popular applications has been in the field of commodity futures trading. Exercises in trading on futures markets were computerized to introduce greater market realism and to provide timely feedback on market activity (Eiler and Goodrich). Students have also used computerized tools to solve simulated farm management problems (see Boehlje, Eidman, and Walker; Curtis). Simulation games have been widely used to help students understand aggregate behavior of the economy (see Attiyeh, Nelson and Doeksen). These games also show students how public policies affect the economy. All of these procedures have one factor in common: they measure the impact of a particular decision. However, simulation procedures have not been widely used in economics to explore the decision-making process—an important part of policy formation.

Applying Simulation

Policy formation simulation was used as a theme for agricultural policy classes. The instructor could choose to pick up with simulation at any time during the course depending on the topic under consideration. The extent to which simulation was used at any one time ranged from simple group discussions to more elaborate simulation games. Simulation was used during approximately 15% of the total class time. To be most effective, simulation should be used after students have been introduced to factors and institutions affecting agricultural policy and the application of economic analyses to evaluate alternative governmental programs. Students are given information on policy formation simulation and assigned roles as senators or aides on the Agriculture and Forestry Committee of the Senate. Each participant represents a certain state and is asked to become familiar with the state he represents. The main goal of each participant is to exploit the situation to his advantage.

Through simulation the committee must make decisions on several agricultural policy issues. Con-

Fred C. White is an associate professor of agricultural economics, University of Georgia.

trasting viewpoints are often presented, and it is the committee's responsibility to reconcile these viewpoints and to develop a consensus statement on the issue. Group discussion, which helps the class to reach its decision, can show how well the students have grasped relevant economic principles.

Two types of games have been used as an integral part of simulation. The policy formation game indicates the problem-solving process by which agricultural policies are created. The second game is the policy simulator, which measures the economic impact of program alternatives. These two games are described in detail.

Policy Formation Game

The class, acting as the Agriculture and Forestry Committee of the Senate, attempts to put together a farm bill generally acceptable to a majority of the senators. Students consider any combination of the major farm commodities in developing the farm bill. The objective of this exercise is to include commodities from enough regions to get adequate regional support for the general farm legislation but without including so many commodities as to lose urban support. The committee's final bill is entered in a computer program to estimate how the actual Senate would vote on the proposed legislation. Results from this computerized analysis indicate which senators would be opposed to the bill and which would support it. Such an analysis of Senate votes gives the students more information on how to design commodity programs.

This simulation game is based on an analysis of Senate votes on 1975 farm legislation designed to increase target prices and support prices for several farm commodities. A discriminant analysis procedure classifies senators as probably belonging to one of three groups: opposing a particular piece of farm legislation, supporting it, or not voting. Social, political, and economic variables that are hypothesized to affect voting behavior are used to delineate the groups. It was assumed that the discriminant functions estimated for votes on a particular commodity (tobacco in this case) could be applied to legislation that would increase support prices or target prices for other commodities by using the percentage of farm income derived from the particular commodity under consideration. The next step involved linking Senate votes for specific commodities together to form a general farm bill concerning several commodities. If a senator voted for legislation to increase support prices for any commodity, he was assumed to support the total farm bill. Other senators would be categorized as opposing the farm bill or not voting, depending upon their stands on legislation for individual commodities.

Added realism in the simulation game was achieved by allowing for different levels of target prices and support prices for each commodity. As long as the farm programs were modest in scope, i.e., having low government costs and little impact on food prices, legislators would be more attentive to agricultural interests. However, as government costs and food prices increased, more opposition to the farm bill would develop. This formulation provided a systematic approach for predicting how senators would vote on farm bills that raised support prices and target prices for various combinations of commodities.

This approach to policy formation provides a classroom atmosphere in which students are free to interact and to express their opinions. The students analyze the simulation exercise in terms of the problem considered, alternative choices, factors influencing a choice, and conflicting roles.

Policy Simulator

Policy models and simulation in current policy research can sometimes be adopted for educational purposes. With a policy simulator game, students must use a problem-solving approach with the following steps: quantify policy goals, formulate theories concerning instruments and targets, and test hypotheses by drawing conclusions from empirical evidence. These steps let students make policy decisions on their own and evaluate the impact of these decisions through the aid of computers.

The particular game that has been used with policy formation simulation deals with the peanut program. Peanuts are one of the few commodities that remain under strict government control. Consequently, the administration and many legislators are interested in modifying or eliminating the program.

This policy simulator is based on a market model of the peanut sector that can be used to explore the implications of changing this program (see Fleming and White). How alternative programs affect production, government and consumer costs, and net farm income is a major consideration. Use of the model was first demonstrated in class by analyzing the peanut sector for 1976–80 under the present price support program. Results show that, if the present peanut program is continued, government costs will increase substantially.

The simulated Agriculture and Forestry Committee of the Senate then explored alternative programs for peanuts. Alternatives considered include marketing quotas, a two-price plan, and a free market policy. Students must consider the impact of these programs on government costs, consumer costs, peanut production, and net farm income.

This approach helps students become aware that policy makers must choose among alternatives. The best choice among these alternatives will depend on two things: how the economic system functions and society's preferences. Forcing students to make a choice from among the alternatives ensures that they understand the effect of the program and have weighed the relative importance of such factors as government costs and farm income.

Evaluation of Simulation as a Teaching Tool

Simulation is an exciting technique to use. The teacher can incorporate debates, field trips, guest lecturers, individual reports, and small group discussions to help make simulation more effective and enjoyable for student learning. It offers flexibility and variety and provides a realistic picture of the way policies are developed, analyzed, and initiated. Simulation can give students the opportunity to think, analyze, and make decisions effectively.

Because students are actively involved in this learning process, they are highly interested and enthusiastic. This teaching method develops students' decision-making abilities because they are asked to give views and feelings on different policy issues. Students must be able to analyze policy situations effectively in order to give intelligent opinions.

A follow-up survey at the end of the course provided an opportunity for students to evaluate the procedure. Student comments highlighted several areas they thought were important. With simulation, students exercised their analyzing capacities to deal with real-world problems and issues, which helped them be better informed in agricultural policy. Simulation provided insights into potential conflicts surrounding policy issues and the mechanisms whereby decisions could be reached. Most importantly, the procedure gave students a better understanding of the intricacies of policy formation.

Using simulation in the classroom required the teacher and student to collect detailed data, do systematic analysis, and organize important relationships. Students improved their understanding of agricultural policy issues and the process that resolves them. Students realized that the roles they played affected their perceptions and evaluations of the situation. Thus, they had a greater appreciation of the policy-making process.

Simulation does, however, have disadvantages. The students have a greater burden than with lectures because they must prepare for the reports, debates, and discussions. When simulation is properly used in conjunction with other techniques, much class time must be devoted to simulation in order for the students to gain the greatest learning benefit. Evaluating student performance can be a problem. Although tests are used to measure student learning, it is difficult to measure everything that the students learn using simulation. The teacher can require that written reports be handed in to evaluate the student's work. Also, through observation, the teacher can subjectively evaluate student performance.

Public policy students must understand the nature of public decisions and how those decisions are made. They must also learn to analyze policy issues and make critical judgments concerning those issues. These educational objectives can best be achieved by actively involving students in the policy-making process. Simulation allows students to participate in this process by casting them in the role of policy makers. Furthermore, students reacted enthusiastically to simulation; they enjoyed the competition in the games and the variety of ways that the issues were introduced and discussed. This approach can effectively be used to supplement more traditional lecture techniques.

Technological Change and Relative Factor Shares in Indian Agriculture: An Empirical Analysis: Comment

Henry Y. Wan, Jr.

In a recent study, Srivastava and Heady (S-H) maintain that technical progress has raised the elasticity of factor substitution in Indian agriculture. They observe that the high-yield varieties require more labor inputs in shorter planting and harvest seasons. Hence, the peak-season wage has risen, but overall employment has not improved. The end result is a reduced labor share in agricultural income.

The S-H estimation procedure is justified only under certain neoclassical assumptions. However, if these assumptions hold, then the S-H formulation in production function estimation is not compatible with the S-H explanation of changing labor shares in assessing the seasonality of labor demand, and, considering the nature of existing technical progress in Indian agriculture, either the S-H sample data are unrepresentative of the Indian agriculture, or the S-H results neither reflect the underlying production technology nor explain the causal determination of the labor share. In what follows, the S-H model formulation and the estimation procedure are reviewed before considering the nature of technical progress in the Indian agriculture.

The Method of Estimation

The S-H study selects two periods: the a priori pretechnological progress epoch of 1954–57 and the a priori posttechnological progress epoch of 1966–70. For each epoch, a constant elasticity of substitution (CES) production function is fitted to the cross-farm microsample data from two Indian districts, Ferozpur and Muzzaffernager. Using cost accounting records, the ratio of labor time (in man-days) to fixed capital (in rupee value) is regressed log-linearly to the ratio of rental rate to average wage rate as well as to dummy variables.

The methodology adopted by these authors has been questioned by various economists in recent years. Weitzman, for example, prefers to estimate the CES production function directly from input-output data. To him, the use of factor prices calls for the making of tenuous assumptions such as individual rationality (in cost minimization) and market perfection. Nadiri and Rosen believe that adjustment costs should be considered in studying the producers' behavior. Aigner, Amemiya, and Poirier and Schmidt consider that the interproducer differences in efficiency should be accounted for.

If, for a particular sample study, the interfarm differences in inertia, inefficiency, or rationality constitute an important yet omitted explanatory variable, then there can be little assurance that findings from the sample are representative for the national economy. Whether the S-H study is biased on this score and what is the nature of the bias, if any, can only be determined by an independent empirical study, a task beyond my present scope. What I shall show is that the S-H study may encounter difficulties in any case.

To begin with, in view of the opinions of Weitzman and others, the procedure used in the S-H study must be justified by the following neoclassical postulates: both individual rationality and market perfection are workable hypotheses; neither adjustment costs nor differences in efficiency or information are of much consequence. Yet in the framework of these assumptions made explicit for the S-H study, several conceptual and logical issues arise.

The Model Formulation

In their statistical work, the authors use both annual labor time and average wage rate in a two-input production function. This approach is justifiable only if the seasonality of labor demand is of little importance. In their policy analysis, the authors recommend rural work programs to guarantee the landless a minimum subsistence income in the face of the technical change. They also comment on the changing seasonality of labor demand. This changing seasonality is not just a matter of descriptive accuracy but also a point of analytical relevance. If the high-yielding varieties do not affect employment levels in all seasons, the observed increase of the average wage rate must imply an increase in the wage bill. *Ceteris paribus*, this in turn increases the

Henry Y. Wan, Jr., is a professor of economics, Cornell University.

While the author takes responsibility for all errors, he appreciates the advice of S. Clemhout and C. Ranade. Credit is also due to a referee who assisted in improving the clarity of the manuscript.

absolute level of the income of the landless, if not their relative shares as well. Therefore, technical progress per se calls for no safeguard to preserve the subsistence of the landless. Rural work programs may be laudable in their own right. They are strictly a *non sequitur* in the present context. Consequently, any need for rural work programs (in response to technical progress) reflects the changing seasonal pattern of labor demand. But to explain the latter, no production theory can succeed if there is only a single labor input. From this viewpoint, a seasonal disaggregation of the labor input not only will bypass the well-known difficulties in aggregation (see Fisher) but also will meet the policy need. The satisfaction of the latter is, after all, the raison d'etre of the S-H exercise.

In short, on the issue of seasonality, the reader is forced to choose between the S-H model formulation and the S-H policy analysis. For the sake of subsequent discussion, I take the S-H two-input production function for granted.

The Nature of Technical Progress

Conceptually speaking, the adoption of any new technology can have one of two outcomes: (*a*) the technical progress is superseding: the old technology is completely displaced, or (*b*) the technical progress is coexistential: the old technology survives beside the new. Nowhere in Asia has the "green revolution" displaced the traditional technology in toto (see, e.g., Dalrymple). In other words, technical progress is coexistential and not superseding. Within the neoclassical framework indispensable for the S-H estimation procedure, this means that two two-input production functions are in use side by side—one for the new technology and one for the old. This may be analyzed in figure 1 below via the Lerner diagram (see, e.g., Findlay and Grubert).

In figure 1, the two broken-line unit "output" isoquants characterize the old and new technologies. (By output is meant value added in the S-H context.) They are representable as $F_i(K_i, L_i, u_i) = 1$, for $i = 0$ (old) and n (new), where $F_i(\cdot)$, K_i, L_i, and u_i stand for the production function, the capital input, the labor input, and the random parameter for technology i, respectively.

Given the pair of values u_0 and u_n, the two technology-specific unit-output isoquants are fixed. Together they determine uniquely first, the common tangent line $P_0 P_m P_n$, whose slope is the coexistential factor price ratio, at which both the old and the new technologies allow the attainment of the same minimum unit cost for the output (both technologies may be adopted by cost-minimizing producers if and only if the market factor price ratio coincides with the coexistential factor price ratio), and second, the least-cost rays OP_0 and OP_n going through origin O and the tangency point P_0 and P_n (between the technology-specific unit-output isoquants $Q_0 P_0$ and $P_n Q_n$ and the line $P_0 P_m P_n$), whose slopes are the least-cost factor proportions under the coexistential factor price ratio. Between OP_0 and OP_n lies the coexistential cone. Both technologies must be adopted if and only if the equilibrium factor proportion ray for the agricultural sector lies in the interior of the $P_0 OP_n$ cone.

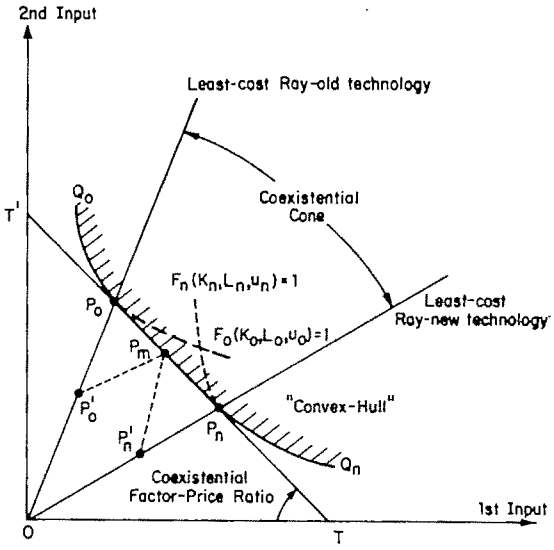

Figure 1. The Lerner diagram

The input-output proportions for a producer using only the old (new) technology are identifiable with the point $P_0(P_n)$. The overall input-output proportions for a producer using both technologies are identifiable with a point P_m between P_0 and P_n.[1] Consider the convex hull for the union of the two technology-specific unit output isoquants. The boundary of this convex hull, the solid locus $Q_0 P_0 P_m P_n Q_n$, is the sectoral unit-output isoquant in the posttechnological change epoch. It shows all the alternative minimum input combinations that can produce one unit of output.

In traditional view, technical progress brings about a new technology unit-output isoquant, which lies uniformly below and leftward of its counterpart under the old technology. For the posttechnological change epoch, the former is the sectoral isoquant. No sample point in this epoch represents any firm using the old technology. While such a view is consistent with both "biased" and "neutral" techni-

[1] A farm with an input vector $\overrightarrow{OP_m}$ has too much (little) first input to use the old (new) technology only. It will allocate inputs, as represented by $\overrightarrow{OP'_0}$ to produce grain with the old technology and allocate the rest, as represented by $\overrightarrow{OP'_n} = \overrightarrow{OP_m} - \overrightarrow{OP'_0}$, to produce grain with the new technology. $\overrightarrow{OP'_0}(\overrightarrow{OP'_n})$ lies along the least cost ray of the old (new) technology. Output from the old (new) technology amounts to $\overrightarrow{OP'_0}/\overrightarrow{OP_0}(\overrightarrow{OP'_n}/\overrightarrow{OP_n})$. Total output can be shown to be one. While there is no technology that is x% old and (100 − x)% new, one can always produce x% of its output with the old technology and (100 − x)% with the new, x being any number between 0 and 100. The resulting convex hull is generated by two isoquants only. This is not an envelope, which can assume a similar form only when a continuum of isoquants are present.

cal progress however defined, it is easily shown that all the Harrod-neutral, Hicks-neutral, and Solow-neutral technical progresses must conform to this traditional view. Atkinson and Stiglitz first pointed out that real life technical progress tends to be localized in nature. Both Jones and Bhagwati amplified this view; under some factor-price ratios, the old technology may remain to be economical. In terms of the Lerner diagram, the two unit-output isoquants cross as in figure 1. Atkinson and Stiglitz paid no attention to the case where both technologies may be simultaneously in use—the case followed through here.[2] Due to the assumptions of constant returns as well as the absence of production externality between the two technologies,[3] the convex-hull construction exists in figure 1. Both technologies will be simultaneously in use if and only if the equilibrium factor supplies to the agricultural sector correspond to an input vector (like $\overrightarrow{OP_m}$) inside the coexistential cone

Under coexistential technical progress, a variation of the sectoral input vector inside the coexistential cone cannot affect the market (i.e., coexistential) factor price ratio or the least-cost factor proportions in either technology. Likewise, the change of the sectoral factor proportions cannot be deduced from the variation of the factor-price ratio. For the sector as a whole, the elasticity of substitution is formally ∞ (due to the uniqueness of the coexistential factor price ratio).

The traditional causal decomposition formula for changing relative shares (S-H equation (4), which follows Brown) is inapplicable to the coexistential technical progress. The only thing to be said is that the ratio of relative shares is the product of the factor-price ratio and the sectoral factor proportions. The former is technologically determined, while the latter is determined by all factors both in and outside the agricultural sector in a general equilibrium fashion. In figure 1, the relative shares ratio may be anywhere between $\overline{TP_n}/\overline{P_nT'}$ to $\overline{TP_0}/\overline{P_0T'}$.

What can be said of the S-H estimation depends upon whether all farms in their sample adopted new technology only (their paper did not provide this information). If the answer is yes, then S-H has estimated the new technology unit-output isoquant. Since the old technology coexists with new in India, their sample is not representative of the economy-wide situation. Whatever they have deduced on factor shares relates only to the ratio of $\overline{TP_n}/\overline{P_nT'}$ and not to the relative shares in Indian agriculture, which relates to a ratio between $\overline{TP_n}/\overline{P_nT'}$ and $\overline{TP_0}/\overline{P_0T'}$ in figure 1. If the answer is no, then their sample is a "mixed bag," some sample points identifiable with P_n, others with P_0, and still others with points like P_m. Their findings do not pertain to the new technology since extraneous observations exist in the sample. Nor does their estimate of the elasticity of substitution portray well the sectoral isoquant, since their sample points correspond to the entire $P_0P_mP_n$ segment. By prior information, it is apparent that within the relevant range such an elasticity is ∞. This is not merely the quantitative question: how accurately do their findings approximate reality? One might maintain that all fitted production functions are approximations anyway. But the culmination of the S-H study is their causal decomposition of the variation in the factor shares. For that task, they rely upon a particular formula—a formula that breaks down with infinite elasticity of substitution (as stated in point 2 above).

Summing up, it appears that for future studies both the seasonality of labor demand and the coexistence of both old and new technologies should be explicitly taken account of on the conceptual as well as empirical planes.

[*Received June 1976; revision accepted September 1976.*]

[2] As shown in Wan, coexistential technical progress is far from being a knife-edge curiosum.

[3] Mutual benefits between apiculture and floriculture exemplifies production externality between different operations. No comparable externality seems to exist between food grain production using the two technologies.

Technological Change and Relative Factor Shares in Indian Agriculture: An Empirical Analysis: Reply

Uma K. Srivastava and Earl O. Heady

Wan provides some interesting and useful extensions and interpretations of the Lerner diagram. It is a useful analysis and provides certain evaluations of our methods and suggestions of policy alternatives.

To incorporate seasonality of labor demand, he suggests a seasonal disaggregation of labor inputs. This disaggregation would certainly be useful if the data were available. However, the data available five years ago were only in terms of total man-days and the wage bill for the crop production period as a whole. Hence, we could not use the suggested approach. However, the average wage bill was still considered relevant since the custom hiring facilities for tractors and other mechanical devices were scarce, and the farmer's decision to substitute capital for labor was considered to be rather independent of the ratio of average wage rates over the crop period to the average price of capital.

New technology in agriculture (high-yielding varieties, mechanical aids, etc.) is never adopted simultaneously by all farmers. In India also the "green revolution" was coexistential in nature in the sense that old technology was used beside the new. Numerous studies have shown that coexistence prevails because of resource constraints (credit facilities in particular) and risk aversion on the part of the continued users of old technology and not because of particular economic advantage of these technologies (Rao; Srivastava, Crown, and Heady). In these circumstances, it does not seem justifiable to use Lerner's diagram even for a theoretical argument on the elasticity of substitution and relative factor shares as restraints. If we examine events over the four years since our paper was written, high-yielding varieties have progressively covered most of the area in the wheat belt where the green revolution took place. It was the small and marginal farmers who were constrained by resources in switching to new technology. Special measures to bring them into the fold of the green revolution have gradually relieved the constraints.

The post-green revolution data used related to high-yielding varieties, while the prerevolution data referred only to local varieties. Despite coexistential technological progress, the available data should reflect changes taking place in the relative factor shares. With the progressive increase in the coverage of high-yielding varieties, one naturally expects changes to be further accentuated. An alternative to our analysis would have been merely "to wait and see." Under the country's vastness and the diversity of soil, climate, human, and other physical resources, our study at best was intended to be regarded as an indicator of changes taking place in the regions experiencing the green revolution. The problem of the poor in regions lacking such technological change was outside our study objectives.

Wan states, "If the high-yielding varieties do not affect employment levels in all seasons, the observed increase of the average wage rate must imply an increase in the wage bill. *Ceteris paribus*, this in turn increases the absolute level of income of the landless, if not their relative shares as well. Therefore, technical progress per se calls for no safeguard to preserve the subsistence level of the landless." The stated objective of our study was to examine the changes in the relative factor shares because these have an important bearing on the prevalent disparities in income between haves and have-nots in Indian agriculture. Any assessment of technology from the point of view of society necessarily needs to be concerned with the undesirable side effects of technological change (Hetman).

Our study admitted the possibility of increased absolute shares to both labor and capital. We observed, however, that the green revolution had brought about a decline in the relative share of labor. This finding itself suggests a possible undesirable consequence of the green revolution. Further, this finding along with additional information (not generated in our study) that the number of people below the poverty line has grown despite the increase in total production and that the bulk of the rural poor are the landless agricultural laborers and small farmers were used to emphasize the need for policy measures designed to augment the incomes of rural poor. The recommendation of a rural works program was mentioned as one such measure but was not intended to be taken as the only policy measure. Subsequently, several studies have supported our findings regarding the decline in the relative shares of labor and a widening of disparities between haves and have-nots in Indian agriculture and the develop-

ing countries (Rao; International Bank for Reconstruction and Development). The root cause has been an unequal distribution of the basic resources—land and finances (Srivastava, Crown, and Heady). Several corrective measures have since been taken in developing countries (International Bank for Reconstruction and Development). In India, more stringent land ceilings, a redistribution of lands to the landless, opening of rural banks specifically for small farmers, landless laborers, and small artisans (Government of India), debt relief, and special development programs (Srivastava and George) are examples.

Interaction of Energy and Food Prices in Less Developed Countries: Comment on a Reply

Emery N. Castle

In a reply to a comment by Konandreas and Green in the August 1976 issue of this *Journal*, Timmer refers to my discussion of his original paper. Both Timmer and I were ambiguous on a particular point. In his reply, Timmer says, "after consideration of possible empirical applications, I now think that the only purpose of the model was to remind us that we all live in an interdependent world where everything affects everything else. It is an elementary point but one that is frequently forgotten. Attempts to quantify it are not likely to be very rewarding" (p. 595). In my original comment on his article I said, "Timmer has surely reached the maximum physical product on his production function in the use of this model. Further extensions may well result in negative marginal returns unless the assumptions of the model are relaxed or unless the model, as formulated, is buttressed by greater treatment of the empirical magnitudes involved" (p. 246). I did not intend to suggest that an attempted empirical development of Timmer's model would necessarily be fruitful, but I believe empirical investigations, utilizing a different theoretical framework, of some of the variables involved would be useful in the interpretation of the model results presented in the original paper. I believe this has been demonstrated by Konandreas and Green. Surely empirical investigation may be of value in interpreting the results of deductive analysis alone.

Emery N. Castle is a senior fellow and vice-president at Resources for the Future.

This point is minor in the context of Timmer's original paper, which I regard in a favorable way. As a methodological issue, the point is not minor, and my original comment should have been more precise. The only empirical work of value does not have to involve the direct application of a model such as Timmer's. Conversely, the value of such a model does not depend on direct empirical application. But this does not mean that we can best interpret the results of such models by ignoring what we have learned about the world by other means, nor does it mean that such models cannot be made more valuable by empirical work that utilizes a different frame of reference.

Books Reviewed

Mellor, John W. *The New Economics of Growth: A Strategy for India and the Developing World.* Ithaca, N.Y.: Cornell University Press, 1976, xv + 335 pp., $11.50.

This ambitious book is bent on convincing the national policy makers of India that there is an employment-oriented high path to national development that will lead to adequate food, employment, and growth. The author views agricultural production and labor mobilization not only as a means to human sustenance and fulfillment but also as instruments in restructuring and accelerating industrial growth. The work is aimed primarily at the refined minds that are, or advise, India's leadership. It also appeals to professional specialists committed to the study of India's contemporary economic scene. At another level, it seeks to communicate with specialists interested in the development of other low-income, densely populated agrarian areas.

The book is carefully organized in parallel with the four major elements that the author insists must be changed if an employment-oriented strategy is to succeed. The first three substantive chapters examine the agricultural sector and India's experience with the green revolution in view of the impacts technical advances can have on the improvement of life for the rural poor. This is in keeping with the first change condition that an employment-oriented strategy "must give priority to increasing agricultural production through investment in new technology" (p. 13).

The next three chapters deal with industrial growth, the industrial sector's uneven capital structure and swings in productivity, and the expansion of demand for industrial goods through rapid growth in the rural sector. This parallels the author's second change condition that an employment-oriented strategy "must reduce the capital requirements per employee in the industrial sector and tap new sources of capital through decentralization of production" (p. 13). The relatively small but highly influential aspects of foreign trade and foreign assistance are taken up in the next two chapters. These support the author's third change condition that "to expedite the decrease in capital intensity, the growth rate of both exports and imports must increase," with an emphasis on capital-intensive imports and labor-intensive exports (p. 13).

After a single-chapter interlude that treats the need for public services in health, nutrition, family planning, education, and the like, the author draws the public service theme into his final chapter dealing with the political basis of national planning and the choice of growth strategy. This emphasis parallels his fourth change condition that, in an employment-oriented strategy, "planning and administrative procedures and institutions must also be decentralized and emphasis switched from regulatory to facilitatory procedures" (p. 13).

The author's method is evidently systematic. There is no reason for a reader to get lost at any point in the book. Not only do the chapters flow from the four necessary conditions of the strategy being advocated but the chapters themselves have parallel internal structure. Each chapter is launched with a summary statement of the substance of its argument. It generally flows from that point into an examination of relevant data, which is usually followed by a speculative essay or commentary.

The ideas in the book are not new, although if India were to adopt the basic employment-oriented strategy, that would be new. The retrospective portions of the various chapters are perhaps the most attractive sections. Not only are they instructive regarding the events of recent decades in India but they introduce the reader to the work of a number of Indian social scientists who are not widely known in the United States. The speculative discussions in the chapters lack comparable strength and are, in places, admittedly theoretical, tending to be equivocal about the future. The book's argument is more an indictment of the failures of the capital-intensity strategies that were implemented during the second and third plan periods (1956–66) than it is a well-argued brief on behalf of a wholesale switch to employment orientation in economic policy. The unhappy part about the work's appearance at this time is that no westerner—even one of the author's standing—is likely to have much influence in India today. The country is presently in no position to accommodate any bold steps in favor of genuine decentralization. Also, the country does not have the resources to put into developing and promoting relevant agricultural technology on a scale similar to the relative levels of investment in agricultural research and extension being made by the industrialized nations. This impedes any changes in the patterns of trade and foreign assistance.

I would estimate that this book will be widely read because of the importance of the subject and the author's excellent credentials. However, it is unlikely to become the guidebook for economic planners that the author intends it to be.

East-West Center

Sjo, John. *Economics for Agriculturalists: A Beginning Text in Agricultural Economics* and *Teachers Aid*. Columbus, Ohio: Grid, 1976, 232 pp. and 128 pp., prices unknown.

From an agriculturalist's point of view, Sjo has written a basic text in economics for agriculturalists. Many traditional topics in agricultural economics are included with the more fundamental material found in contemporary microeconomic textbooks. Sjo's book is about one-third the size of the latter, but what has been gained in cost reduction and printing efficiency may be an illusion, as beginning students in underdivision classes ponder the underlying relationships and theory that the text material is based upon.

The book is one of contrasts. The introduction to each chapter and reading lists are excellent. The chapters covering descriptive material on the changing structure of agriculture, the role of agriculture in the development process, and emerging problems in agriculture are generally good, although sometimes lacking in depth. The major weaknesses of the book are in its theoretical presentation and its theory-application linkups. For instance, in early chapters Sjo stresses the point that, while traditional agricultural economics was primarily concerned with production problems, increasing emphasis is being placed on market-oriented problems. However, as the text develops, most topics that would be included in an intermediate production economics text are presented, while demand analysis and market structure are given very cursory treatments. Co-ops and marketing orders are briefly mentioned, but no analysis is attempted to show how they improve a farmer's profit position. Also, detailed flow diagrams of market channels are presented, but any theoretical development of how products move through these channels (such as the concept of derived demand) is missing.

Brevity of presentation takes its heaviest toll in the theoretical sections. The consumer demand discussion is confusing as it jumps from ideas of individual demands, to market demands, back to indifference curves, to income and substitution effects, to income elasticities, to price elasticities, and to demand facing a firm in pure competition in about ten short pages. Will the student become confused and not grasp the more fundamental concepts? The topics included in the production section may be too ambitious for an introductory text. Unfortunately, an understanding of production theory is made more difficult because of several incorrect examples and illustrations. For example: (*a*) on page 66, the author says the beginning of stage 2 is where average product is maximum; however, the example shows stage 2 beginning at a different point; (*b*) in showing the impact of price changes on output, the stages of production are ignored altogether; (*c*) in moving from production functions to cost curves, the cost curves are drawn incorrectly, since cost is plotted with units of input on the horizontal axis; (*d*) in the figure on page 82, the profit area is incorrectly illustrated; and (*e*) the author defines average product to be an efficiency measure of productivity but describes regions of increasing constant and decreasing productivity using the marginal physical product function.

In the market structure portion of the book, it is implied that forces of supply and demand only operate to determine prices in perfect competition. It is difficult to visualize the firm-market relationships in this section, and students may be persuaded that there is a greater degree of head-to-head competition as one moves from perfect competition to monopolistic and oligopolistic competition. In the discussion of monopoly the author incorrectly defines the marginal cost curve of a monopolist to be his supply curve, and marginal revenue is presented in such a manner that there is no evident relationship between it and the demand curve. Finally, while the author describes oligopoly to be the predominant form of market structure in the United States, his discussion of oligopoly pricing is very limited.

Brevity of presentation in other chapters may also lead to misconceptions on the part of students such as: profit is related to producing products with the largest consumer demand; the more preferred a product, the greater is its income elasticity; if per unit costs are decreasing, a firm should automatically use more inputs to increase its profit; advances in technology increase the profits of producers; a business aware of diseconomies will cut back its size to increase profits; and the slope of a supply curve is a measure of price responsiveness of producers.

The well-done *Teacher's Aid* summarizes the purpose of each chapter, identifies important terms, and lists study questions, problems, quizzes, and test questions and answers. After reading the *Teacher's Aid*, a contemporary advertisement came to mind: "leave the driving to us." Some may be very tempted to "leave their thinking to Sjo."

Economics for Agriculturalists introduces the world of economics in an agricultural setting and presents a good summary of the changing structure of American agriculture and its importance in our economy. However, we feel that considerable reworking is needed in the theory sections if the book is to be used in an introductory course in agricultural economics.

Sorenson, Vernon L. *International Trade Policy: Agriculture and Development*. International Business and Economic Studies, Graduate School of Business Administration, Michigan State University, 1975, xix + 290 pp., $6.00 paper.

This book was written for classroom use and treats international agricultural trade in a global context, including issues of concern to both advanced and less developed countries. The focus is strongly on

agricultural trade policy rather than on trade theory or trade research. The book is written at a level appropriate for an international agricultural trade course for upperclassmen and beginning graduate students. Teachers of agricultural policy and agricultural development will also find individual chapters appropriate as supplementary readings for their courses.

The beginning two chapters survey international trade policy and trends in trade flows in a historical context. Emerging trade problems of both advanced and less developed countries are identified.

Chapter 3 presents basic trade theory concepts relevant for agricultural trade analysis, while chapter 4 contrasts arguments for free trade versus trade restriction and discusses the interrelations between domestic agricultural policy and trade policy. Partial equilibrium tools to analyze the economic and welfare effects of protection are presented. These two chapters comprise the theoretical core of the book. While the level may be adequate for beginning graduate students, more advanced students would require additional supplementary readings in trade theory.

The next two chapters contain a useful description and analysis of domestic agricultural policy and its relation to trade in advanced countries, particularly the European Community and the United States. Multilateral trade negotiations under the General Agreement on Tariffs and Trade are also discussed. These two chapters should prove useful to students of both agricultural policy and international trade.

Agricultural trade issues of the less developed countries are treated in chapters 7 through 10. Chapter 7 reviews the relationship between trade and development and discusses the objectives of the U.N. Conference on Trade and Development. The next chapter describes several proposals for international commodity agreements and compensatory financing schemes, followed by a review of the barriers to the developing countries' exports and a discussion of the roles of trade liberalization and customs unions. This section ends with chapter 10 on trade sector planning. These four chapters would make useful supplementary readings for a course in agricultural development.

The final chapter attempts to pull together the various topics treated in the book and to put current trade policy issues in perspective.

The principal strengths of the book lie in its descriptions and analyses of domestic agricultural and trade policies in both developed and developing countries and in its discussion of the issues related to the recent calls for a new international economic order by the developing countries. The basic elements of international trade theory relevant for understanding agricultural trade are reviewed in chapters 3 and 4. However, I am concerned with an apparent antitheory bias, which runs through the book. This is unfortunate, especially for students at the formative stage who have not yet acquired an appreciation for the role of theory in empirical economic research. International trade theory offers a rich source of hypotheses for empirical trade studies, which is underplayed by Sorenson.

Sorenson also downplays the importance of general equilibrium analysis, arguing for a partial equilibrium framework for empirical work (chap. 3). However, general equilibrium feedback effects of a policy change may be important, as is demonstrated in chapter 10 in a discussion of trade sector planning. Where these effects are important, general equilibrium effects need to be taken into account in empirical studies.

In his treatment of trade policy issues, particularly those relating to the developing countries, Sorenson attempts to give a very balanced treatment in which all viewpoints are represented. However, in his attempt to be fair and unbiased, Sorenson has been somewhat uncritical in presenting arguments whose merits must be judged on other than economic criteria. In addition, he tends to overlook the impediments that the developing countries themselves have put in the way of their exports, such as exchange rate overvaluation and quantitative controls.

Two topics of current trade policy interest are not treated in the book. One concerns the effect of exchange rate changes on agricultural exports. When prices in several different countries are converted to a common currency for comparison, no indication is provided concerning what exchange rates were used (or whether they might be interpreted as equilibrium rates). The second issue that is not treated concerns the implications of monopsonistic importers, such as centrally planned economies, confronting a competitive export market.

It is no discredit to Sorenson that he has not solved all these problems. He has brought together in a well-organized and clearly written volume a wealth of information on international agricultural trade policy, which should serve as a textbook and useful reference for students and teachers of agricultural trade policy in both developed and developing countries.

Schertz, L. P., A. R. Stevenson, and A. M. Weisblat. *International Training in Agricultural Economic Development.* New York: Agricultural Development Council, 1976, viii + 118 pp., $5.00.

Stout, B. A. *Energy for Agriculture: A Computerized Information Retrieval System.* 4th ed. Agricultural Engineering Department, Michigan State University, Sept. 1976, 317 pp., $5.00.

Swierenga, Robert P. *Acres for Cents: Delinquent Tax Auctions in Frontier Iowa.* Westport, Conn.: Greenwood Press, 1976, xix + 262 pp., $14.95.

Thrall, R. M., E. Heady, T. Schad, A. K. Schwartz, and R. G. Thompson. *Economic Modeling for Water Policy Evaluation.* Amsterdam: North-Holland Publishing Co., 1976, xvii + 261 pp., $20.95.

Upton, Martin. *Agricultural Production Economics and Resource-Use.* New York: Oxford University Press, 1976, x + 357 pp., $23.00.

Winter, George R. *Protein Efficiency in Canada.* Montreal: Canadian Livestock Feed Board, 1975, ix + 330 pp., $5.50, $3.50 paper.

Announcements

Annual Meeting, 1977

The annual meeting of the American Agricultural Economics Association will be held jointly with the Western Agricultural Economics Association on 31 July–3 August at the Town and Country Hotel, San Diego, California. Overall responsibility for the program is shared jointly by Kenneth Farrell, president of the AAEA, and William Martin, president of the WAEA. John Redman, secretary-treasurer of the AAEA, is in charge of the arrangements. Correspondence concerning the 1977 meetings should be directed to the appropriate person. Information regarding the facilities, contributed papers program, etc., has been sent to all AAEA members. Further program information, along with registration and reservation forms, will be forthcoming in presidential letters and from the secretary-treasurer. Contributed papers information is repeated in this issue.

Symposium on Southern Agriculture

A symposium, "Southern Agriculture Since the Civil War," is to be held in Starkville, Mississippi, in June 1978. Joining in sponsoring the meeting are the Agricultural History Society, the U.S. Department of History, and Mississippi State University. Persons wishing to present papers at the symposium may correspond with Wayne D. Rasmussen, Agricultural History Group, Economic Research Service, U.S. Department of Agriculture, Washington, D.C. 20250, or with Roy V. Scott, Department of History, Mississippi State University, Mississippi State, Mississippi 39762.

Contributed Papers for the Annual Meeting

Contributed papers are invited for the 1977 AAEA meeting at San Diego. No subject matter restrictions are placed on contributed papers other than required relevance to the discipline of agricultural economics. In the past, session titles have included a wide range of subjects such as natural resources, firm growth, farm management, water, marketing, energy and the environment, international trade and development, and other topics of interest to agricultural economists. Papers submitted are considered for presentation and are titled after all papers are reviewed for relevance, quality, and potential contribution to knowledge. Availability of meeting rooms at the San Diego meetings will probably limit the total number of contributed papers to between sixty and seventy, in contrast to more than one hundred during the last several years. Because a more complete review is required, papers should be forwarded by first class mail and must be postmarked no later than midnight, 1 April 1977.

Each author is limited to one contributed paper for which he is the sole or senior author. Contributions by graduates and undergraduate students are solicited. The papers, including tables, footnotes, and references, should not exceed twelve double-spaced pages. Authors are urged to follow the *Journal* guidelines in preparing manuscripts for review. Each manuscript must be accompanied by a fifty-word abstract.

Presentation of contributed papers (as well as presentation and/or discussion of invited papers and invited addresses) at annual meeting is limited to AAEA members, except in special cases where the condition is waived by the president.

Copies of the abstract will be available at registration and in advance of the session as an aid to participants. Also, the abstract of each contributed paper that is accepted and presented in the sessions will be printed in the 1977 proceedings issue of the *Journal*. Authors are invited to submit their contributed papers to the *Journal* editor for consideration at a later date, subject to the normal review process.

Each manuscript for the contributed papers sessions must be accompanied by facts needed by session chairmen to introduce the authors to the audience. A minimum set of information includes name, title, institutional affiliation, advanced degrees, and a brief employment profile.

The following dates are important. By 1 April 1977 three copies of the manuscript, a fifty-word abstract, and a biographical sketch must be submitted, postmarked no later than midnight, to cochairmen Daniel D. Badger or Harry P. Mapp, Jr., Department of Agricultural Economics, Oklahoma State University, Stillwater, Oklahoma 74074. By 15 June 1977 authors are notified of the status of their papers. The AAEA meetings are held in San Diego, California, 31 July–3 August 1977.

Personnel

Agricultural Development Council

Appointment: William L. Collier, formerly with the Department of Agricultural and Resource Economics, University of Hawaii, is a council associate in Bogor, Indonesia.

University of Arizona

Appointment: Roger A. Selley, formerly with the Ford Foundation, is an assistant professor.
Resignation: John C. Day, former associate professor, is an agricultural economist, Technical Assistant Bureau, Agency for International Development, Washington, D.C.

University of Arkansas

Resignation: James A. Bogart, former research assistant, is a field representative, Federal Land Bank, Pine Bluff, Arkansas.

University of California, Berkeley

Appointments: Peter Berck, Ph.D. M.I.T., and **Michael Hanemann,** Ph.D. Harvard University, are resource economists.

University of California, Davis

Appointment: Rulon D. Pope, Ph.D. University of California, Berkeley, is an assistant professor.

University of Chicago

Appointment: G. S. Tolley is the coeditor of a new journal, *Resources and Energy*.
Honors: D. Gale Johnson, professor of economics and provost, is a member of the American Academy of Arts and Sciences; **Theodore W. Schultz,** professor emeritus, received the Elmhirst Medal from the International Agricultural Economists Association, July 1976, and is a trustee for the International Agricultural Development Service.

Clemson University

Resignation: Clayton Grant, visiting assistant professor, is a teacher in the Department of Business, Brenau College, Gainesville, Georgia.

NRED: National Economic Analysis Division of the Economic Research Service; SRS: Statistical Reporting Service.

Colorado State University

Leave: Robert A. Young is on a research assignment with the Department of Farm Management, Lincoln College, Canterbury, New Zealand.

University of Connecticut

Leave: Carlos Stern, associate professor, is on leave with the U.S. Geological Survey, Reston, Virginia.
Retirement: Arthur W. Dewey, former professor, has left after thirty years of service.
Honor: Stewart Johnson, professor emeritus, received the Distinguished Member Award from the Northeastern Agricultural Economics Council for 1976.

Cornell University

Appointment: William G. Lesher is acting assistant professor of land use policy, 1976–77.

University of Florida

Appointments: William D. Mulkey, formerly at Clemson University, **Thomas H. Spreen,** formerly at Purdue University, and **George B. Wall,** formerly at North Carolina State University, are assistant professors of food and resource economics.

University of Georgia

Appointment: Chung-Liang Huang, Ph.D. Virginia Polytechnic Institute and State University, is an assistant professor, Georgia Experiment Station.

Iowa State University

Appointment: Kenneth E. Stone is an assistant professor of economics.
Resignation: Gordon C. Rausser, former professor of economics, is a professor of economics, Harvard University.

Kansas State University

Appointments: Randy Baden, formerly with Garden City Junior College, is an area extension specialist-economics stationed in Garden City; **Bryan W. Schurle,** Ph.D. Ohio State University, is an assistant

professor of farm management-research and teaching.
Return: David W. Norman is back after acting as chairman, Department of Agricultural Economics and Rural Sociology, Ahmadu Bello University, Nigeria, since 1965.
Resignation: J. J. Kropf, former extension economist, is with Livestock Business Advisory Services, Kansas City, Missouri.

Michigan State University

Appointment: Peter Matlon, Ph.D. Cornell University, is an assistant professor in the international programs area.
Resignations: William R. Bentley, former professor of resource economics and management, is the manager of Forestry Research, Crown Zellerbach Corporation, Camas, Washington; **William Crowley,** ERS, USDA, is entering private business.

University of Minnesota

Appointments: Duty D. Greene, M.E. North Carolina State University, is a research specialist in farm management and production economics research; **Andrea J. Lubov,** Ph.D. Washington State University, is a research associate in public services.
Honor: E. Fred Koller, professor emeritus, received the 1976 National Cooperative Month Education Award for his outstanding talents as a teacher and educator of sound cooperative concepts.

University of Missouri

Leave: Brice Ratchford is a visiting professor in extension economics-marketing and agricultural policy, Kansas State University.

University of Nebraska

Appointment: Dean Linsenmeyer, Ph.D. Michigan State University, is an assistant professor of agricultural marketing.

University of New Hampshire

Appointment: Bruce E. Lindsay is an assistant professor of regional economics, Institute of Natural and Environmental Resources.

Oklahoma State University

Appointment: Gregg L. Parvin, M.S. University of Arkansas, is an assistant in research.

Oregon State University

Appointment: Kenneth C. Gibbs, former associate professor, University of Florida, is with the School of Forestry.
Resignation: Timothy M. Hammonds, associate professor, is a research director, Super Market Institute.

Pennsylvania State University

Appointment: James G. Beierlein is an assistant professor of agricultural business management.

Prairie View A&M University

Resignation: M. A. Soliman, former associate professor, Department of Economics and Geography, is a professor of economics, Kuwait University, Kuwait.

Purdue University

Appointments: Martin T. Pond is the acting program director of community development; **James Pratt** is a research assistant; **Ram D. Singh** is a research specialist.
Return: Ramon B. Wilson, professor, is back from Washington, D.C.
Resignation: Joann C. Mullen is a teacher, Morton Memorial School, Knightstown, Indiana.
Honor: Robert C. Keen is vice-president of the International Board of Directors, Farm House Fraternity.

University of Rhode Island

Appointments: Nancy E. Bockstael and **Jon G. Sutinen,** Ph.D.'s University of Rhode Island, are assistant professors in resource economics.
Leave: John Gates is on sabbatical leave for one year with the Office of Extended Jurisdiction, National Marine Fisheries Service, Washington, D.C.

Southern Illinois University

Resignation: Gordon Langford, former associate professor, Department of Agricultural Industries, is in private industry, Denver, Colorado.

U.S. Department of Agriculture

Appointments in SRS: Donald W. Barrowman is the assistant director, Research Division, and a USDA clearance officer; **Richard P. Small** is the statistician in charge of the Florida State Statistical Office; **Carroll D. Spencer** is the statistician in charge of the Wisconsin State Statistical Office.

Utah State University

Appointment: Allen LeBaron is the codirector, Office of Sectorial Planning, Ministry of Agriculture, Bolivia, Utah State University Contract.
Return: Morris D. Whitaker is back after serving as codirector, Office of Sectoral Planning, Ministry of Agriculture, Bolivia.

Washington State University

Leaves: Desmond O'Rourke, associate professor, is on leave with the Economics and Social Research Institute, Dublin, Ireland, through Aug. 1977; **Norman K. Whittlesey,** professor, is on leave with Environmental Economics, NRED, ERS, USDA, Colorado State University, through Aug. 1977.

West Virginia University

Appointment: Virgil Whetzel, ERS, USDA, Colorado State University, is with the Division of Resource Management.

University of Wyoming

Appointment: James L. Stephenson, M.S. University of Wyoming, is a research associate.

Other Appointments

Paul K. Blakeley, Ph.D. Virginia Polytechnic Institute and State University, is an agricultural economist, Agricultural Canada, Ottawa.

Faustino Ccama, M.S. Virginia Polytechnic Institute and State University, is at the Universidad National Tecnica Del Altisplano, Puno, Peru.

Thomas J. Cusack, Ph.D. Oregon State University, is a research economist, Agricultural Institute, Dublin, Ireland.

Demitri Damianos, Ph.D. Virginia Polytechnic Institute and State University, is with the Research and Planning Division, Agricultural Bank of Greece.

Daniel Hartley, M.S. University of Wyoming, is with the Wyoming Department of Agriculture, Cheyenne.

John E. Schefter, Ph.D. Oregon State University, is with the U.S. Geological Survey, Reston, Virginia.

James R. Sinclair, M.S. University of Wyoming, is with Cargill, Inc., Minneapolis, Minnesota.

Cynthia Tinberg, Ph.D. Michigan State University, is an associate economist in regional economics, Midwest Research Institute.

Roberto Cristian Zegers-Prado, Ph.D. University of Minnesota, is at the Universidad Austral de Chile, Valdivia, Chile.

Obituary

Marshall D. Harris

Marshall D. Harris died of a heart attack 17 August 1976 in Shelbyville, Kentucky. He had retired from the Economic Research Service, U.S. Department of Agriculture, in 1973 and returned to his native state after thirty-nine years of federal service. In the last nineteen years of service he was affiliated with the Agricultural Law Center at the Law School, University of Iowa, which he was instrumental in helping to form.

Harris was born in Kentucky in 1903 and received his undergraduate education at the University of Kentucky, graduating in 1926. He did graduate work at Kentucky and Illinois and received his Ph.D. in 1942. In 1946, he received a study grant by the General Education Board to assume residency at Duke University while rewriting his doctoral thesis, which was later published by the Iowa State College Press in 1953 as *Origin of the Land Tenure System in the United States*.

Harris's federal service began in 1933 as a special investigator for the Farm Credit Administration, USDA. He subsequently worked for the Agricultural Adjustment Administration, USDA; Natural Resources Board, U.S. Department of the Interior; Resettlement Administration, Farm Security Administration, Bureau of Agricultural Economics, and the Economic Research Service.

During his career, Harris was closely involved with land tenure and agrarian reform and was a pioneer in interdisciplinary legal-economics research. Always a prolific writer, at one count he had well over 100 publications to his credit. In addition to *Origins*, he was involved in editing and producing numerous other books including *Family Farm Policy*, *Agrarian Reform and Moral Responsibility*, *Town and Country Churches and Family Farming*, and *Land Tenure Research Workshop* (all coedited with Joseph Ackerman). With Harold Halcrow, he edited *Modern Land Policy*, and with Ackerman and Clawson, *Land Economics Research*. He wrote a large number of Agricultural Law Center monographs and also prepared USDA extension material on Farm Leasing that is still being used today. His major research efforts at the time of his retirement was the locus of entrepreneurship in agriculture. He received the USDA's Superior Service Award in 1961.

JOURNAL OF THE AMERICAN STATISTICAL ASSOCIATION

March 1977 Table of Contents

Presidential Address, Franklin A. Graybill

Applications

Relationships—and the Lack Thereof—Between Time Series, with Special Reference to Money and Interest Rates ..... *David A. Pierce*
Covariance Analysis of Heart Transplant Survival Data ..... *John Crowley and Marie Hu*
Considerations in Measuring Partial Association for Ordinal Categorical Data ..... *Alan Agresti*
Comparison of Stopping Rules in Forward "Stepwise" Regression ..... *Robert B. Bendel and A. A. Afifi*
Two Methods for Examining the Stability of Regression Coefficients ..... *Kenneth Garbade*
Cubic Splines as a Special Case of Restricted Least Squares ..... *A. Buse and L. Lim*
Maximum Likelihood Estimation in Random Coefficient Models ..... *Warren T. Dent and Clifford Hildreth*
Tables of Exact Confidence Limits for Differences and Ratios of Two Proportions and Their Odds Ratios ..... *Donald G. Thomas and John J. Gart*

Theory and Methods

A Simulation Study of Alternatives to Ordinary Least Squares ..... *A. P. Dempster, Martin Schatzoff and Nanny Wermuth*
Comment on "A Simulation Study . . ." ..... *Bradley Efron and Carl Morris*
Comment on "A Simulation Study . . ." ..... *Arthur E. Hoerl*
Comment on "A Simulation Study . . ." ..... *David M. Allen*
Comment on "A Simulation Study . . ." ..... *A. F. M. Smith*
Comment on "A Simulation Study . . ." ..... *Christopher Bingham and Kinley Larntz*
Comment on "A Simulation Study . . ." ..... *Ronald A. Thisted*
Rejoinder to Comments on "A Simulation Study . . ." *A. P. Dempster, Martin Schatzoff and Nanny Wermuth*
Statisticians Are Fairly Robust Estimators of Location ..... *Daniel A. Relles and William Rogers*
Bayes Linear Estimators of the Intensity Function of the Nonstationary Poisson Process ..... *M. L. Clevenson and J. V. Zidek*
Identification of Dynamic Regression (Distributed Lag) Models Connecting Two Time Series ..... *Larry D. Haugh and G. E. P. Box*
Generalized Inverses, Wald's Method, and the Construction of Chi-Squared Tests of Fit ..... *David S. Moore*
Is the Tail Area Useful as an Approximate Bayes Factor? ..... *James M. Dickey*
A Note on a Reformulation of the S-Method of Multiple Comparison ..... *Henry Scheffe*
Comment on "A Note on a Reformulation . . ." ..... *Richard Olshen*
Rejoinder to Olshen's Comment ..... *Henry Scheffe*
On a Unique Consistent Solution to the Likelihood Equations ..... *Robert V. Foutz*
On the Effect of Stratification when Two Stratifying Variables Are Used ..... *Ib Thomsen*
Bounds on Absorption Probabilities for the m-Dimensional Random Walk ..... *William E. Wecker and Thomas E. Morton*
Recovery of Interblock Information for Designs With Groups of Correlated Blocks ..... *Thomas R. Bement and George A. Milliken*
On Characterizations of the Exponential and Geometric Distributions by Expectations ..... *Kong-Ming Chong*
A Differential Equation Approach to Linear Combinations of Independent Chi-Squares ..... *A. W. Davis*
Estimation of Quantiles of Exponential Distributions with Minimum Error in Predicted Distribution Functions ..... *C. A. Robertson*
One-Way Layout for Counts and the Exact Enumeration of the Kruskal-Wallis H Distribution with Ties .. *Jerome H. Klotz and James Teng*
A Two-Sample Test for Independence in 2 × 2 Contingency Tables with Both Margins Subject to Misclassification ..... *Richard P. Chiacchierini and Jesse C. Arnold*
An Approximate Test of Markov Chain Lumpability ..... *M. U. Thomas and D. R. Barr*
Testing a Sequence of Observations for a Shift in Location ..... *Douglas M. Hawkins*
Two-Stage Least Squares: In Which Direction Should the Residuals Be Minimized? ..... *T. W. Anderson and Takamitsu Sawa*
Robustness of Stein's Two-Stage Procedure for Mixtures of Normal Populations ..... *Saul Blumenthal and Z. Govindarajulu*
Nonparametric Estimation of Ratio of Scale Parameters ..... *Helen T. Bhattacharyya*
Sequential Procedures for Testing a Two-Sided Alternative Hypothesis Concerning the Parameter of the Binomial Distribution ..... *L. Billard*
On a Class of Partially Sequential Two-Sample Test Procedures ..... *Douglas A. Wolfe*
A Bivariate Model for the Distribution of b_1 and b_2 ..... *L. R. Shenton and K. O. Bowman*
On F-Independence for Nonnegative, Bounded-Sum Variables When the Bound is Large ..... *Ian R. James*
Intermediate Simultaneous Inference Procedures ..... *Yosef Hochberg and German Rodriguez*

Economic Development and Cultural Change

Founded in 1952, **Economic Development and Cultural Change** has consistently investigated the factors contributing to economic growth and change from a variety of perspectives—social, demographic, political, historical, and anthropological. Confined by neither discipline nor method, the journal attempts a broad theoretical exploration of the mechanisms and implications of development in countries throughout the world.

Featured in the October 1976 issue

Simon Kuznets, Demographic Aspects of the Size Distribution of Income: An Exploratory Essay

Simon Kuznets, the recipient of the third Nobel Prize in Economics for his work on the economic growth of nations, has contributed this significant article discussing the implications of demographic components for the conventional measurements of income distribution and for customary comparisons of income inequalities over time.

Resource Allocation and Productivity in National and International Agricultural Research

Edited by **Thomas M. Arndt, Dana G. Dalrymple,** and **Vernon W. Ruttan**

For those concerned with the productivity of agricultural research and with allocation of resources for that research in developing countries, this volume provides a comprehensive analysis of the implications of science and technology for agricultural development. The forty contributors—natural and social scientists and research administrators—review such matters as present organization and management of international and national research systems and discuss strategy and management issues that will affect future productivity. $25.00

A SURVEY OF AGRICULTURAL ECONOMICS LITERATURE

Volume 1, Traditional Fields of Agricultural Economics, 1940s to 1970s

edited by Lee R. Martin, Professor of Agricultural and Applied Economics, University of Minnesota

This is the first volume of a comprehensive three-volume survey of agricultural economics literature since World War II. This volume contains surveys of the literature in seven broad areas, prepared by ten outstanding authorities.

Subjects and authors of the reviews in Volume I:

Farm Management and Production Economics, 1946-1970. Harald R. Jensen, University of Minnesota.

The Analysis of Productive Efficiency in Agricultural Marketing: Models, Methods, and Progress. Ben C. French, University of California, Davis.

Policy for Commercial Agriculture, 1945-71. George E. Brandow, Pennsylvania State University.

Postwar Policies Relating to Trade in Agricultural Products. D. Gale Johnson, University of Chicago.

Agricultural Price Analysis and Outlook. William G. Tomek and Kenneth L. Robinson, both of Cornell University.

Agricultural Finance and Capital Markets. John R. Brake, Michigan State University, and Emanuel Melichar, Division of Research and Statistics, Board of Governors of the Federal Reserve System, Washington, D. C.

Technical Change in Agriculture. Willis Peterson, University of Minnesota, and Yujiro Hayami, International Rice Research Institute, Manila, Philippines.

Published for the American Agricultural Economics Association by the University of Minnesota Press.

The regular price of Volume 1 is $25.00. Members of the American Agricultural Economics Association may order copies at a special price of $18.00 ($20.00 outside the U.S.), postpaid. This special price offer is available to AAEA members for one year following publication of the book. Send your order now, using the order form below. Books will be shipped when ready.

JEI JOURNAL of ECONOMIC ISSUES

Published by the Association for Evolutionary Economics and Michigan State University

The two-issue symposium on the Chicago School, appearing in the December 1975 and March 1976 issues, has been reprinted with four additional chapters covering a constructive critique.

The Chicago School of Political Economy
paperbound *537 pp./$8.00*

Contributions from other recent issues include:

Michel De Vroey, "The Transition from Classical to Neoclassical Economics"; M. L. Myers, "Adam Smith's Concept of Equilibrium"; Jörg Baumberger, "No Kuhnian Revolutions in Economics"; James Street, "The Technological Frontier in Latin America"; Victor Goldberg, "On Positive Theories of Redistribution"; and Ron Stanfield, "Limited Capitalism, Institutionalism, and Marxism."

Annual membership dues are: $6.00 per year for three years, student; $12.00, individual; and $16.00, library. Add $2.50 per year for subscriptions outside North America. Inquiries to: AFEE/JEI Fiscal Office, 509-J Business Administration Building, The Pennsylvania State University, University Park, PA 16802.

european review of agricultural economics

Managing editor: Jan de Veer
Landbouw-Economisch Instituut
Conradkade 175 · The Hague · Netherlands

ERAE is a quarterly journal designed to serve as a forum for discussions about the development of theoretical and applied agricultural economy research in Europe and for stimulating ideas regarding the economic problems of agriculture in Europe and other parts of the world.
ERAE also promotes discussion on national research use, protection of the environment, marketing of agricultural products and development of rural areas.
ERAE offers original articles as well as full or abstracted articles which have already appeared in national publications and in other languages and, in addition, shorter features (research notes, book reviews, comments, communications) to supplement the main contents and insure that the most recent information available is covered.

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter to the editor, the author must state (*a*) that the material has not been published, and is not being published or being considered for publication elsewhere; (*b*) that the material in the manuscript, so far as the author knows, does not infringe upon other published material protected by copyright; and (*c*) that he or she is aware that each issue of the *Journal* is copyrighted, that submission of a manuscript to the *Journal* gives the AAEA the right to publish and to copyright the material, and that republication elsewhere at a later date is contingent upon written approval from the *Journal* editor. If the applicability of point (*a*) is unclear, the author should provide an explanation of the publication status of the manuscript.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
12. **Page charge.** All published contributions, with certain specific exemptions, are subject to a charge of $40 per printed page or fraction thereof. Exemptions are granted for book reviews, papers invited by the editor, the presidential address, the fellow's lecture, and those invited addresses and papers receiving explicit written exemption from the AAEA president. If an author has no financial support from an employer or granting agency to cover the charge, an exemption may be granted. Instructions for making payment and for requesting an exemption are provided with galley proofs. If the charge is honored, 100 reprints are provided. An employer cannot request a financial exemption while agreeing to buy reprints.

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal.*

The subscription rate for institutions and nonmembers is $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal,* changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.

An article, note, or other material appearing in the *American Journal of Agricultural Economics* may not be republished in full or in part without the express written permission of the editor.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except that concerning "Books Reviewed" and "Books Received," should be addressed to the editor, William G. Tomek, Department of Agricultural Economics, Cornell University, Ithaca, New York 14853.

Communications concerning books for review and books submitted for announcement in the *Journal* should be sent to the book review editor, Francis E. Walker, Department of Agricultural Economics and Rural Sociology, Ohio State University, Columbus, Ohio 43210.

Market Price Effects of Technological Change on Income Distribution in Semisubsistence Agriculture

Yujiro Hayami and Robert W. Herdt

The impact of a technologically induced rightward shift in the supply function of a commodity grown and partly consumed by semisubsistence farmers is examined. In closed-economy, free market situations, the distribution of economic gains between consumers and producers depends on the proportional shift of the supply function, proportion of the commodity marketed, and elasticities of demand and supply for the commodity. Differences in adoption and marketable surplus between large and small farmers result in differential benefits, but over a range of parameter values, small farmers gain as much or more than large farmers when supply shifts faster than demand.

Key words: income distribution, subsistence agriculture, supply shifts, technological shifts.

Since the emergence of new cereal technology in Asia, the impact of technological change on income distribution has become a major concern. Attention has focused on a number of issues suggesting that technological advance may contribute to an increased concentration of income. The arguments cited usually include faster rates of adoption by "big" compared with "small" farmers or by owners compared with tenants, a labor-saving bias in the technology that reduces labor's share, nonadaptability of technological innovations to all geographic areas, a tendency for public services to be available to big farmers but not to small, and incentives for landlords or wealthy farmers to consolidate small holdings into larger units, thereby promoting a polarization of the rural population.[1]

While neither denying nor affirming these arguments (they appear to hold in some cases and not in others), the purpose of this paper is to examine a neglected impact of technological change on income distribution—the market price impact. The essence of the argument is as follows. Technical progress for a commodity implies a downward shift in the cost function and hence a rightward shift in the supply function, which with a downward sloping demand curve results in an increase in economic welfare through the consumption of a larger quantity at a lower cost.

Distribution of the gains in economic welfare between consumers and producers depends on the price elasticities of demand and supply for the commodity. In economies where farm producers sell almost all their output and farm product demand is price inelastic, consumers are the main beneficiaries of farm technological process, with farmers finding themselves trapped on a technological "treadmill." (For a classical treatment, see Cochrane.) However, when a major fraction of the commodity is consumed in the households of producers and not traded in the market place, some of the consumers' surplus from technical progress is internalized by those producers. Since they sell some fraction of their output, they are called semisubsistence producers.

If demand is price inelastic and prices are permitted to adjust to market forces, the de-

Yujiro Hayami is on the faculty of economics, Tokyo Metropolitan University, Japan, and Robert W. Herdt is an agricultural economist at the International Rice Research Institute, Los Baños, Philippines.

The authors acknowledge the assistance of Masao Kikuchi in the mathematical development of the model. The helpful criticisms of Vernon Ruttan, Robert Evenson, Jim Ryan, Reed Hertford, T. W. Schultz, and D. G. Johnson are acknowledged. Any remaining shortcomings in the paper are the responsibility of the authors.

[1] These arguments are mentioned by Wharton, Falcon, Johnston and Cownie, and Staub and Blase. More emotional exposition of some are provided by Frankel and by Griffen. Little empirical evidence is cited by any of the authors.

gree of consumers' surplus internalized by farm producers is inversely related to the proportion of output sold. If the commodity's price is fixed by government policies or determined by the international market, then the technological change may not result in any price change. In such a case, the distribution of benefit will accrue to producers in direct proportion to their sales.

In this paper, a model is developed that incorporates this special attribute of semisubsistence production into an analysis of the relation between technical change and income distribution in a closed economy, both among sectors and within sectors. The model is applied to data on rice economy of the Philippines to illustrate the potential influence of technological development in rice production technology.

The total income distribution effect of the introduction of technological advances will depend on the impact such an introduction has on the factor shares and on the ownership distribution of the factors as well as on its impact on market prices. While recognizing the importance of the former issues, in this paper we focus on the latter.

A Model of Income Distribution

Critical considerations in the analysis of the distribution of gains from technical progress in the production of a subsistence crop are: (*a*) the subsistence crop is produced by a mass of small producers so that its market can be approximated by perfect competition, (*b*) the subsistence crop is a "necessity" good characterized by a low price elasticity of demand, (*c*) a major portion of the subsistence crop output is consumed by the producers' households and a minor portion is sold in the market, and (*d*) the price for the crop is set by demand and supply in the domestic market.

Intersectoral Distribution

Figure 1 shows the demand and supply schedules of a subsistence crop in the market. The vertical line (D_HH) represents the demand curve of producers for home consumption. Considering the subsistence crop as a basic need, producers' households are assumed to consume a given quantity of their produce irrespective of prices and to sell the rest in the market. (In a later section, this assumption is modified by making consumption responsive to output.) The market demand for the product is represented by D_MD; the horizontal difference between D_MD and D_HH measures the quantity purchased by nonfarm households. The total demand for the crop is represented by D_HD_MD.

The supply schedules before and after a technical change occurs are S_0O and S_1O. Corresponding to the shift in the supply schedule, the market equilibrium point moves from A to B. Nonfarm consumers enjoy the

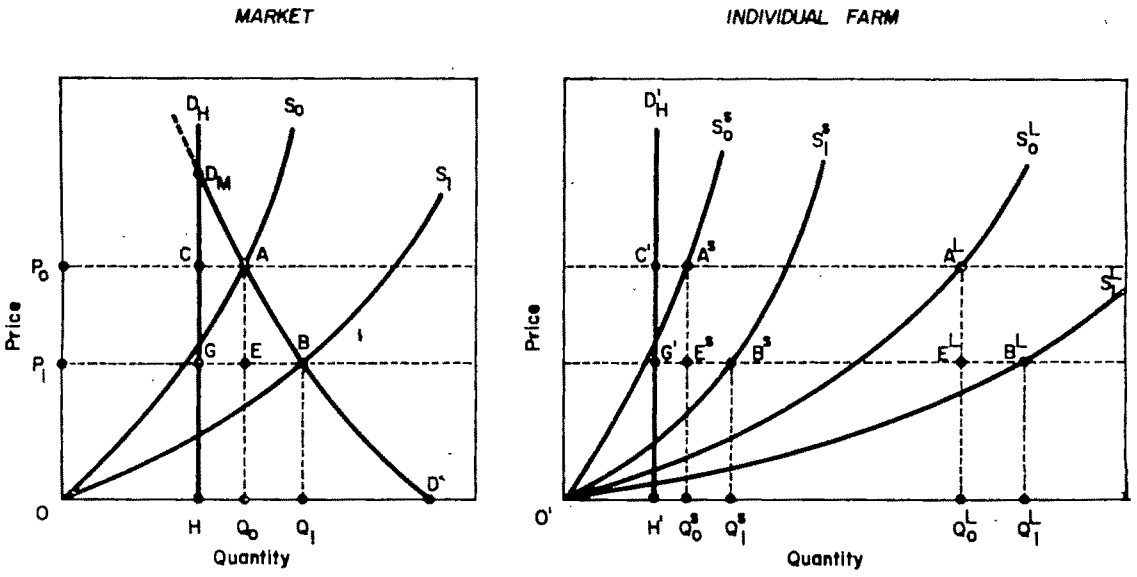

Figure 1. The impact of technological change in a subsistence crop

increased consumption (HQ_0 to HQ_1) at the reduced price (OP_0 to OP_1)—consumers' surplus increases by area $ACGB$. On the other hand, producers' cash revenue changes from area $ACHQ_0$ to area $BGHQ_1$, while producers' home consumption stays the same, OH. The cost of production changes from area AOQ_0 to BOQ_1.

Assuming that the real income value of home consumption of the product by producers is represented by the quantity consumed, income changes to producers are reflected in changes in their cash income.[2] Whether producers' cash income (revenue minus cost) is increased by the technical change depends on the demand and supply functions. However, clearly, the larger is the ratio of home consumption, the more likely it is that producers' incomes will increase. For example, if agriculture is completely commercialized and home consumption is zero (D_HH coincides with the vertical axis), the reduction in cash revenue is area AP_0P_1E − area BEQ_0Q_1, which is clearly much larger than area $ACGE$ − area BEQ_0Q_1, which is the case of subsistence agriculture. In either case the change in cost is measured by area AOQ_0 − area BOQ_1. On the other hand, the increase in consumers' surplus is clearly smaller in subsistence agriculture (area $ACGB$) than in commercialized agriculture (area AP_0P_1B).

Approximate the relevant range of the total demand schedule (D_HD_MD) by a typical constant elasticity demand function:

$$q = cp^{-\eta}, \tag{1}$$

where p and q are, respectively, the price and the quantity demanded of a subsistence crop; c includes income and other demand shifters; and η is the price elasticity of demand.

Assume a constant elasticity supply function as

$$q = bp^{\beta}, \tag{2}$$

where p and q are the price and the quantity supplied; b includes supply shifters except technical change; and β is the price elasticity of supply. Assuming a k% shift in the supply schedule due to technical progress, the new supply function (S_1O) can be expressed as

$$q = b(1 + k)p^{\beta}. \tag{3}$$

If the equilibrium price and quantity before the technical progress are denoted as p_0 (= OP_0) and q_0 (=OQ_0), respectively, those after the technical change, p_1 (= OP_1) and q_1 (= OQ_1), can be approximated as[3]

$$p_1 \cong p_0\left(1 - \frac{k}{\beta + \eta}\right) \tag{4}$$

and

$$q_1 \cong q_0\left(1 + \frac{\eta k}{\beta + \eta}\right), \tag{5}$$

provided that k is a relatively small percentage change.

Consumers' gain in terms of the increase in consumers' surplus is expressed as

$$\begin{aligned} \text{(6)}\quad \text{Area } ACGB &= \text{area } AP_0P_1B - \text{area } CP_0P_1G \\ &= \int_{p_1}^{p_0} cp^{-\eta}\,dp - q_0(1 - r)(p_0 - p_1) \\ &\cong p_0q_0\frac{kr}{\beta + \eta}, \end{aligned}$$

where r is the ratio of marketable surplus (total output minus home consumption) to total output, i.e., $r = HQ_0/OQ_0$. Equation (6) shows that consumers' gain from the technical progress is larger as r is larger or as the production of the crop is more commercialized.

Correspondingly, the cash revenue of producers will change by

$$\begin{aligned} \text{(7)}\quad &\text{area } BEQ_0Q_1 - \text{area } ACQE \\ &= p_1(q_1 - q_0) - q_0r(p_0 - p_1) \\ &\cong p_0q_0k\frac{(\eta - r)}{\beta + \eta}, \end{aligned}$$

which indicates that producers' cash revenue will increase if r is smaller than η. In other words, the less commercialized is the production, the larger is the gain in producers' cash revenue (or the smaller is the loss).

Meanwhile, the cost of production will change by

[2] One could carry through the analysis by including the consumers' surplus of farm producers as the measure of their welfare. Using that approach does not provide any fuller understanding because what producers gain as consumers from the technical change they lose as producers. Producers' consumers' surplus increases by the area CGP_1P_0, while their producers' surplus is reduced by the same amount. Because concern is focused on the changes induced by technological advance, the alternative analytical approach does not change the conclusions of the analysis.

[3] Solve for p_0 in terms of the parameters by equating equations (1) and (2); solve for p_1 in terms of the parameters by equating equations (1) and (3); the value of the ratio of p_0/p_1 can be approximated as equation (4) using a Taylor's expansion; substituting equation (4) into equation (3) and again using a Taylor's expansion gives equation (5).

(8) area BOQ_1 − area AOQ_0 =

$$[p_1q_1 - \int_0^{p_1} (1 + k)bp^\beta \, dp]$$

$$- (p_0q_0 - \int_0^{p_0} bp^\beta dp)$$

$$\cong p_0q_0 \frac{k^\beta(\eta - 1)}{(1 + \beta)(\beta + \eta)}.$$

Since the price elasticity of demand (η) for the basic staple cereals is small, certainly less than one, cost of production will decline.

Thus, with technological progress, the cash income of producers (income accrued to producers' owned factors) will change by

(9) Change in cash revenue − change in cost

$$\cong p_0q_0k \frac{\eta - r + \beta(1 - \eta)}{(1 + \beta)(\beta + \eta)},$$

which indicates that the gains of producers will be larger if r is smaller, i.e., if the production of the crop is less commercialized.

The above relations clearly indicate that technological progress in the production of a subsistence crop in a less commercialized closed economy would not only benefit consumers but also is likely to benefit producers.

Distribution among Producers

The right-hand diagram in figure 1 illustrates the changes in equilibrium points of two types of individual farm producers corresponding to changes in market equilibrium point in the left-hand diagram. The supply curves of small and large farms are represented by $O'S_0^S$ and $O'S_0^L$, respectively, before the technological advance, which correspond to OS_0 in the left-hand diagram. The supply schedules of the small and large producers after the change in technology (OS_1) are represented by $O'S_1^S$ and $O'S_1^L$. It is assumed here for convenience that the quantity of home consumption is the same for both small and the large farmers, which does not affect the essence of the argument.

Corresponding to the technological change and the change in market prices, the equilibrium of the small producer moves from A^s to B^s, with the corresponding changes in cash revenue by area $B^sE^sQ_0^sQ_1^s$ − area $A^sC'G'E^s$ and in cost by area $B^sO'Q_1^s$ − area $A^sO'Q_0^s$. Likewise, the equilibrium of the big farmer moves from A^L to B^L, accompanied by the changes in cash revenue by area $B^LE^LQ_0^LQ_1^L$ − area $A^LC'G'E^L$ and in cost by area $B^LO'Q_1^L$ − area $A^LO'Q_0^L$. The net effect on producers' income depends on the relative changes in revenue and cost, which in turn depend on the price elasticities of supply of individual producers' relative to the aggregate demand elasticity.

The aggregate price elasticity of supply (β), which determines the market prices (in the left-hand diagram), is the weighted average of the price elasticities of supply of individual producers, i.e., $\beta = \sum_i w_i\beta_i$, where β_i is the price elasticity of supply of the ith producer ($i = L$ for large producer and $i = S$ for small producer), and w_i is the share of the ith producer in total output. Likewise, the rate of shift in the aggregate supply is an average of the rates of supply shift of individual producers, i.e., $k = \sum_i w_ik_i$.

Applying the same procedures as for the changes in intersectoral income distribution (equations (7) through (9)), approximation formulae for analyzing the impacts of a k% shift in the aggregate supply function on the ith producer are derived as follows:

(10) Change in cash revenue

$$\cong p_0q_{0i}(k_i - k\frac{\beta_i + r_i}{\beta + \eta}),$$

(11) Change in production cost

$$\cong p_0q_{0i}\frac{\beta_i}{1 + \beta_i}(k_i - k\frac{1 + \beta_i}{\beta + \eta}),$$

and

(12) Change in income

$$\cong p_0q_{0i}(k_i - \frac{k_i\beta_i}{1 + \beta_i} - \frac{kr_i}{\beta + \eta}),$$

where q_{0i} and r_i represent, respectively, the output and the marketable surplus ratio of the ith producer before the shift in the supply function. Equations (10) through (12) reduce to equations (7) through (9) if $k_i = k$ and $\beta_i = \beta$.

Whether technical progress in the subsistence crop has a positive effect on the income of the ith producer, i.e., whether equation (12) takes a positive value, depends to a large extent on the magnitudes of k_i and β_i relative to k and β. Clearly, as r_i takes smaller values, the increase in income is larger (or the decline is smaller). In other words, the income position of farmers who sell a small portion of their produce in the market will improve relative to

those who sell a large fraction, given a technical change.

The model is also readily applicable to the analysis of the impact of technical change on the relative incomes of landlords and tenants. If rent is paid in kind as a fixed proportion of output, say, one-half, the supply curve of a tenant can be obtained by shifting the supply curve of an owner-operator horizontally left by 50%. However, if costs are shared in the same proportion by the landlord, the supply curve of the tenant is identical with that of an owner-operator's curve. In this case, the changes in revenue, cost, and income of both landlords and tenants due to the technological change are one-half of the changes in the case of owner-operator, which can be expressed by multiplying equations (10) through (12) by one-half. The major difference between the landlords and the tenants would be expressed by the values of r. The marketable surplus ratio of the small share tenant will be very small, whereas the ratio of the large landlords will be nearly one.

In the case of leasehold tenure, in which the rent is paid in kind in a fixed quantity, the marketable surplus of the tenant is reduced by the quantity of the rent (which could be shown by a rightward shift of $D'_H H'$ in figure 1). Assuming that the landlords sell the whole quantity collected as rent in the market, the aggregate market supply would be the same as in the case of an owner-operator. The change in income of the tenant due to the technical change can be expressed by equation (12) with a smaller value of r. On the other hand, the income of the landlords receiving a fixed quantity of rent in kind would be reduced by the rate of decline in the market price of the produce as expressed by equation (4).

Under the conditions specified, the model demonstrates the fact that technical progress in the production of a subsistence crop has the effect of narrowing the income gap between large farms (or landlords) and smaller farms (or tenants), thereby contributing to a more equal income distribution in the rural sector.

Distribution among Consumers

As shown in equation (6), technical change in production of the subsistence crop represents a clear gain in the economic welfare of urban consumers. The impact of a lowered price of staple food on the welfare and income of urban households depends on the importance of the staple in their expenditure pattern. Poor classes normally consume greater quantities of such products than wealthy; hence, they benefit more.

Suppose that total income (y) is spent either for the food staple (S) or for other commodities (x) as $y = p_s q_s + p_x q_x$, where p_s, p_x, q_s, and q_x represent, respectively, the prices and the quantities of the food staple and the other commodities. Then the percentage change in real income due to a decline in the price of the food staple can be approximated by

$$\frac{\Delta y}{y} = e \frac{\Delta p_s}{p_s}, \tag{13}$$

where $e = p_s q_s / y$ is the ratio of expenditure for the food staple to total household income.

According to equation (4), the percentage change in the market price of the subsistence food crop corresponding to a k% shift in the supply curve is $k/(\beta + \eta)$. Therefore, the percentage increase in real income is approximated by

$$\frac{\Delta y}{y} \cong \frac{ek}{\beta + \eta}. \tag{14}$$

Since e is inversely correlated with per capita income, the decline in the price of food staple due to the technical progress in its production has the effect of equalizing income among urban consumers.

Application to Philippine Rice Economy

In this section the model developed previously is applied to the rice economy of the Philippines in order to demonstrate the distributional implications of technical progress in major subsistence crops.

The Philippines represent an especially relevant case for the present analysis. Rice is the most important subsistence crop in the country, planted in about 3 million hectares, more than 30% of total crop area. It is a typical subsistence crop, in contrast with commercial export crops such as sugarcane and coconuts, which are mainly produced for sale. Rice is also the most important food staple, comprising more than 70% of cereal food consumption on a national basis and up to 90% of cereal consumption in some regions.

Because of the establishment of the International Rice Research Institute in the Philippines and the relatively well-developed local

research and extension capacity, the impact of the new technology has been as significant in the Philippines as in any rice-producing country. The area planted in the new high-yielding varieties has exceeded 55% of lowland rice area (Herdt and Wickham). From the very beginning of the development of new rice technology, its impact on income distribution has been a major concern. For example, Ishikawa has observed that the emergence of large commercial rice farms in Central Luzon coincided with the diffusion of high-yielding varieties and attributed the tendency towards polarization to the high cash requirement of the new technology. Thus, the application of this model to the Philippine rice economy is especially relevant.

Intersectoral Distribution

Estimates of the price elasticity of demand for rice by Nasol based on aggregate time-series data range from -0.23 to -0.47 with a mode of -0.3. In this analysis, the values 0.2, 0.3, and 0.4 are used for η in order to assess the impacts of different price elasticities on the results.

The price elasticity of rice supply was analyzed by Mangahas, Recto, and Ruttan. Their estimates of short-run and long-run elasticities are distributed around mean values of 0.3 and 0.5, respectively. In this analysis, 0.3 and 0.5 are used as boundary estimates for β.

On a national basis, average yields of new rice varieties grown under lowland conditions were 11% higher than yields of traditional varieties between 1968 and 1973 (Atkinson and Kunkel). Ten percent is adopted as the value for k, the shift in the aggregate supply function, for convenience of illustration.

National data on the quantity of marketable surplus of rice is not available. A sample survey in Central Luzon, "the rice bowl of the Philippines," conducted by the International Rice Research Institute, provides a beginning approximation (Toquero et al.). An average of 40% of production was sold by farmers. In addition, a major portion of rent in kind (17% of total output) was also probably sold in the market by landlords. However, farmers in Central Luzon are known to sell more on the market than do most Philippine farmers. Therefore, it seems reasonable to assume that the aggregate marketable surplus ratio (r) is 0.4.

The results of applying the specified parameters into equations (4) through (9) are summarized in table 1. A 10% increase in the supply function due to technical progress results in a price decline of 10% to 20% and an increase in quantity of 3% to 6%. Consumers' surplus rises by 4% to 8%, while producers' cash revenue declines slightly. However, the reduction in revenue is more than compensated for by the reduction in production cost, resulting in an increase in the cash income of producers of 1% to 2% (except the case of $\eta = 0.2$ and $\beta = 0.3$).

Calculations using the average price and quantity prevailing in the Philippines between 1969 and 1971 and the most probable values of $\beta = 0.4$ and $\eta = 0.3$ show total benefits of the new technology worth about 150 million pesos per year, with 80% going to consumers and 20% to producers. The effects on income distribution would be quite different in a commercial agriculture. If r is assumed to equal one, consumers gain twice the value of the new income stream—half from the benefits of the lower cost technology and half as a transfer from producers whose losses equal the benefits of the technology.

Table 1. Calculated Percentage Change in Consumers' Surplus and Producers' Income Due to Technical Progress in Rice Production in the Philippines

	Percentage Changes with the Specified Parameters					
	$k = 0.1$			$r = 0.4$		
	$\eta = 0.2$		$\eta = 0.3$		$\eta = 0.4$	
Changes in	$\beta = 0.3$	$\beta = 0.5$	$\beta = 0.3$	$\beta = 0.5$	$\beta = 0.3$	$\beta = 0.5$
Price	−20.0	−14.3	−16.7	−12.5	−14.3	−11.1
Quantity	4.0	2.9	5.0	3.8	5.7	4.4
Consumers' surplus	8.0	5.7	6.7	5.0	5.7	4.4
Producers' cash revenue	−4.0	−2.8	−1.7	−1.2	0	0
Production cost	−3.7	−3.8	−2.7	−2.9	−2.0	−2.2
Producer's cash income (producers' surplus)	−0.3	1.0	1.0	1.7	2.0	2.2

Hence, while technological progress in a fully commercial agriculture facing an inelastic demand would result in an income transfer from farm producers to urban consumers, technological progress does not have such a strong distributional impact on producers in a semisubsistence agriculture. While a major gain from technological progress in rice production goes to nonfarm consumers, the aggregate income of producers also likely increases.

Distribution within the Rural Sector

The analysis of the impact of new technology on the income distribution among producers is based on equations (10) through (12). The problem reduces to a comparison of changes in revenue, cost, and income of small and large farmers in response to the price decline resulting from the shift in the aggregate supply function.

Large and small farmers differ mainly in the proportion of output they sell (r). The earlier study mentioned indicated that about half the sample farmers in Central Luzon sold less than 25% of their produce, and less than 5% of the farmers sold more than three-quarters. For the sake of illustration, $r = 0.2$ is assumed for small farms and $r = 0.8$ for the large farms.

There is no empirical evidence that there are differences in the adoption of technical progress in rice production (k) and in the price elasticity of rice supply (β) among small and large farmers in the Philippines. Rather, the available evidence seems to support the hypothesis that there is no significant difference in the rate of diffusion of the new high-yielding varieties and in the resulting increase in yield between the small and the large producers (Mangahas, Miralao, and de los Reyes; International Rice Research Institute). Considering the highly divisible nature of the new seed-fertilizer technology, it seems reasonable to expect that the technical progress has been neutral with respect to farm scale. However, in order to test the effect of differential rates of technical progress, an analysis was carried out based on two alternative assumptions: (*a*) the same shift from technical progress for different size classes ($r_s = r_L = r = 10\%$), and (*b*) a shift from technical progress of the larger farmers twice that of the small farmers ($r_s = 7$, $r_L = 14$, and $r = 10\%$).

There is also a possibility that larger farmers with a greater capacity for investment financing find it easier to adjust their production to the long-run equilibrium point. Considering such a possibility, two further alternative assumptions are specified: (*a*) both the large and the small farmers have the same price elasticity of supply ($\beta_s = \beta_L = \beta = 0.4$), and (*b*) the supply elasticity of the large farmers reach the long-run level, while the elasticity of the small farmers remains at the short-run level ($\beta_s = 0.3$, $\beta_L = 0.5$, and $\beta = 0.4$).

Four cases occur from the possible combinations of values of k_i and r_i. The results are summarized in table 2. In all cases, technical progress improves the income position of small farms while that of the large farms deteriorates. In cases 1 and 2, the 10% shift in the supply function increases the incomes of small farms and reduces the incomes of large farms by more than 4%, respectively. However, even when the shift from technical prog-

Table 2. Calculated Differential Impacts of Technical Progress in Rice Production on Small and Large Farmers in the Philippines

	Parameters Specified			Percentage Changes in		
	$k = 0.1$	$\eta = 0.3$	$\beta = 0.4$	Cash	Production	Cash
	r_i	β_i	k_i	Revenue	Cost	Income
Case 1						
Small farms	0.2	0.4	10	1.4	−2.9	4.3
Large farms	0.8	0.4	10	−7.1	−2.9	−4.2
Case 2						
Small farms	0.2	0.3	10	2.9	−2.0	4.9
Large farms	0.8	0.5	10	−8.6	−3.8	−4.8
Case 3						
Small farms	0.2	0.4	7	−1.4	−3.7	2.3
Large farms	0.8	0.4	14	−3.1	−1.7	−1.4
Case 4						
Small farms	0.2	0.3	7	−0.1	−2.7	1.6
Large farms	0.8	0.5	14	−4.6	−2.5	−2.1

ress of large farms is twice that of small farms (cases 3 and 4), the income of the small farms improve and the income of the large farms decline by about 2%, respectively. Improved technology is a force tending to equalize incomes among rice producers.

The results also provide insight on the relative changes in income position between tenants and landlords as discussed above simply by regarding small farms as tenants and large farms as landlords. However, the income-equalizing effect of the new technology between tenants and landlords is likely much greater than shown because r for most share tenants is smaller than 0.2 and r for large landlords must be close to 1.0.

Distribution among Nonfarmers

As shown earlier, the major gains in economic welfare from the development of new rice technology are captured by nonfarm consumers. Their gains vary with the fraction of total expenditure devoted to rice. By applying data on the share of rice in the total expenditure of urban households for different income classes in the Philippines (Bureau of Census and Statistics) to equation (14) with $\beta = 0.4$ and $\eta = 0.3$, the differential impacts of technical change on the real income of urban households were calculated. A 10% shift in the rice supply function results in a 4% increase in real income for households with less than 1,500 pesos annual income (about $250). The same change increases the real income of the highest income classes with more than 15,000 pesos annual income by only 1%. The relative gain in real income is larger for the households of low-income workers. These benefits of new rice technology are not only captured by urban workers but also by landless farm workers for whom rice is a major item of household expenditure.

Relaxing the Assumption of Fixed Home Consumption

The most restrictive assumption in the preceding analysis is that of fixed home consumption of the commodity by farmers' households. There have been few attempts to estimate the price response of home consumption. A recent study for rice in the Philippines based on a sample survey of the same farmers for three consecutive years shows that the effect of price changes on home consumption of rice is not statistically significant and home consumption rises significantly in response to increases in output, although it tends to level off at high outputs. The results of the regression analysis were confirmed by a motivation survey on the disposition of rice output (Toquero et al.).

At least in the case of rice in the Philippines, it is reasonable to assume that home consumption is not price responsive and can be approximated by a vertical line such as D_HH in figure 1. However, D_HH does not stay stable but shifts to the right as output increases OQ_0 to OQ_1. The rightward shift in the home consumption schedule implies a shift to the right in the total demand schedule by the same amount, as represented by the shifts from D_HH to $D_H^*H^*$ and from D_HD_MD to $D_H^*D_M^*D^*$ in figure 2. Corresponding to this shift, the market equilibrium after the introduction of new technology will be established at B^* instead of at B.

The consumers' surplus (of nonfarm consumers), assuming the increase in home consumption in response to output increase, is represented by area $B^*D_M^*G^*$. Since $D_H^*D_M^*D^*$ is parallel with D_HD_MD, area $B^*D_M^*G^*$ is equal to area WD_MZ. Therefore, the increase in consumers' surplus due to the technical change under the assumption of fixed home consumption by producers' households is larger than when home consumption increases in response to output increases by area $BWZG$.

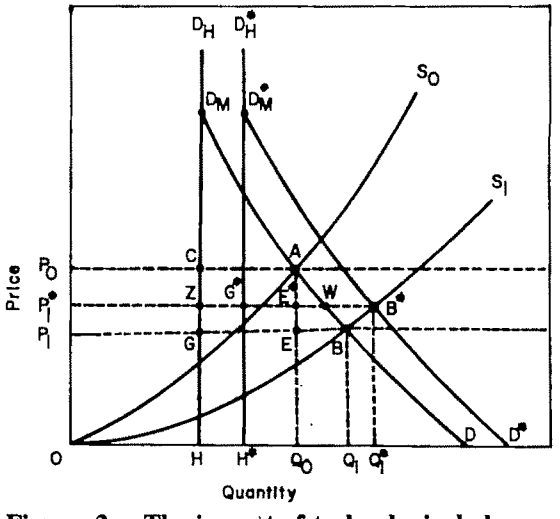

Figure 2. The impact of technological change in a subsistence crop under the assumption of variable home consumption

Correspondingly, the assumption of the fixed home consumption is likely to produce an overestimation of producers' cash revenue by the difference between area $B^*G^*H^*Q_1^*$ − area $ACHQ_0$ and area BEQ_0Q_1 − area $ACGE$ and to produce an underestimation of the cost of production by area $BQ_1Q_1^*B^*$.

Define m as the percentage shift in the total demand function corresponding to the increase in home consumption (Δh), i.e.,

$$(15) \qquad m = \frac{HH^*}{OQ_0} = \frac{\Delta h}{q_0} \cong \frac{\Delta q}{q_0}\delta(1 - r),$$

where $\delta \left(= \frac{\Delta h}{\Delta q}\frac{q}{h}\right)$ is the elasticity of home consumption with respect to output. Assuming that m is approximately constant for the relevant range of analysis, the total demand schedule ($D_H^*D_M^*D^*$) can be approximated by

$$(16) \qquad q = c(1 + m)p^{-\eta}.$$

The equilibrium price and quantity after the change in technology and including the adjustment in home consumption resulting from the output increase can be obtained by solving the simultaneous system consisted of equations (3) and (16) as follows:

$$(17) \quad p_1^* \cong p_0\left(1 - \frac{k}{\beta + \eta} + \frac{m}{\beta + \eta}\right)$$

and

$$(18) \quad q_1^* \cong q_0\left(1 - \frac{\eta k}{\beta + \eta} + \frac{\beta m}{\beta + \eta}\right).$$

Correspondingly, the changes in consumers' surplus, producers' cash revenue, and production cost due to the change in technology are recalculated for the case of variable home consumption as

(19) Change in consumers' surplus

$$= \text{area } WD_MZ - \text{area } AD_MC$$
$$\cong p_0q_0\left(\frac{kr}{\beta + \eta} - \frac{mr}{\beta + \eta}\right),$$

(20) Change in producers' cash revenue

$$= \text{area } B^*G^*H^*Q_1^* - \text{area } ACHQ_0$$
$$\cong p_0q_0\,\frac{k(\eta - r)}{\beta + \eta} - \frac{m(\eta - r) - m(k - m)}{\beta + \eta},$$

and

(21) Change in production cost

$$= \text{area } B^*OQ_1^* - \text{area } AOQ_0$$
$$\cong p_0q_0\left[\frac{k\beta(\eta - 1)}{(1 + \beta)(\beta + \eta)} + \frac{\beta m}{\beta + \eta}\right].$$

The second terms of each expression represents the additional effect when the assumption of fixed home consumption is relaxed.

In order to evaluate the effect, the value of m is required. Equation (18) implies

$$(22) \qquad \frac{\Delta q}{q_0} \cong \frac{\eta k + \beta m}{\beta + \eta}.$$

Substitution of the above expression into equation (15) yields

$$(23) \qquad m \cong \frac{k\eta\delta(1 - r)}{\beta + \eta - \beta\delta(1 - r)},$$

which is calculated as 1.2% for the following values of the parameters: $\eta = 0.3$, $\beta = 0.4$, $k = 10\%$, $r = 0.4$, and $\delta = 0.4$.[4]

Calculations of the consumers' surplus and producers' cash income for the two assumptions about producers' home consumption are compared in table 3. The assumption of fixed home consumption may contribute to a small overestimation of consumers' gains. The welfare loss of producers from the reduction in

[4] Specification of δ is based on Toquero et al.

Table 3. Calculated Percentage Changes in Consumers' Surplus and Producers' Income Due to Technical Progress in Rice Production for Two Assumptions on Producers' Home Consumption

Change in	Fixed Home Consumption	Variable Home Consumption	Variable Minus Fixed Home Consumption
Price	−14.3	−13.6	1.7
Quantity	4.3	5.0	0.7
Consumers' surplus	5.7	5.0	−0.7
Producers' cash revenue	−1.4	−1.1	0.3
Production cost	−2.8	−2.3	0.5
Producers' cash income	1.4	1.2	−0.2
Producer's' home consumption	0	2.0	2.0

Note: The variables are assumed to have the following values: $\eta = 0.3$, $\beta = 0.4$, $k = 0.1$, $r = 0.4$, and $\delta = 0.4$.

cash income seems more than compensated for by increased home consumption. The magnitude of possible effects on consumers' welfare and producers' cash income are sufficiently small so that the basic conclusion on intersectoral income distribution is not affected. Also, since the effect on prices is small, the conclusion on income distribution within the urban sector remains unaltered.

Consider the implications of the assumption of fixed home consumption on the income distribution between large and small farmers. Individual farmers will try to maximize their profit for the market price determined by equation (17). Since the elasticity of home consumption of rice with respect to output declines as output rises, the rate of increase in home consumption corresponding to the increase in output due to technical progress would be different for large and small farmers; it is likely to be smaller for large farmers than for small farmers. The percentage increase in aggregate home consumption in response to the increase in aggregate rice output is the weighted average of the percentage for the large and small producers, i.e., $m = \Sigma w_i m_i$.

Applying the same procedures as for the case of fixed home consumption, a formula was derived for analyzing the impacts of change in technology on the ith producer for the assumption of variable home consumption as follows:

(24) Change in cash revenue

$$\cong p_0 q_0 \left[k_i - \frac{k(\beta_i + r_i)}{\beta + \eta} - m_i + \frac{m(\beta_i + r_i)}{\beta + \eta}\right],$$

and

(25) Change in production cost

$$\cong p_0 q_0 \frac{\beta_i}{1 + \beta_i}\left(k_i - k\frac{1 + \beta_i}{\beta + \eta} + m\frac{1 + \beta_i}{\beta + \eta}\right),$$

where m_i is defined as

$$(26) \qquad m_i = \frac{\Delta hi}{q_{oi}} = \frac{\Delta q_i}{q_{oi}}\,\delta_i(1 - r_i),$$

where q_{oi} and r_i are the quantity of total output (= consumption) and the marketable surplus ratio before the introduction of new technology, respectively; Δq_i and Δh_i are the changes in the quantities of total output and home consumption due to the introduction of the technology; and δ_i is the output elasticity of home consumption of the ith producer.

Since individual producers increase output along their supply schedules in response to the change in market price from p_0 to p_1^*, which is given by equation (17), the rate of increase in output can be approximated by

$$(27) \qquad \frac{\Delta q_i}{q_{oi}} \cong k_i \frac{\beta_i (m - k)}{\beta + \eta}.$$

The variable m_i is given as

$$m_i = \left[k_i + \frac{\beta_i (m - k)}{\beta + \eta}\right]\delta(1 - r_i).$$

The different estimates of the impacts of technical progress on large and small farmers for different assumptions on producers' home consumption behavior are compared in table 4. For the case of variable home consumption, the home consumption of small producers is assumed to be highly responsive to output increases with $\delta_s = 0.6$, whereas the home consumption of large producers is in saturation, i.e., $\delta_L = 0$.

Compared with the case of fixed home consumption, the favorable impact of the technical change in promoting a more equal distribution of cash income is less dramatic if changes are allowed in home consumption for small producers. However, even in case 4 with the higher rate of technical progress and the larger capacity for supply adjustment of larger farmers, the impact of technical progress on the distribution of cash income is in the direction of promoting equality. While small farmers' cash income position stays fairly stable, larger farmers incur substantial losses. Economic welfare of small farmers clearly increases since their consumption of rice increases (last column of table 4), while their cash income remain nearly constant.

The results of table 4 show clearly that, if the specification of δ's is correct, technical progress in rice production will contribute to the welfare of small producers by increasing their rice consumption and will result in a reduction of income to large commercial farmers and/or landlords; the part of their income reduced will be transferred to the urban poor and the landless rural workers in the form of a lowered price of the basic consumption good. Thus, the conclusion that technical progress in the production of subsistence crops in a semisubsistence economy has the effect of

Table 4. Calculated Percentage Change in Consumers' Surplus and Producers' Incomes for Small and Large Farmers with Two Assumptions on Producers' Home Consumption (Percentage Change)

	Fixed Home Consumption Case[b]			Variable Home Consumption Case[c]			
	Cash Revenue	Production Cost	Cash Income	Cash Revenue	Production Cost	Cash Income	Home Consumption
Case 1[a]							
Small farms	1.4	−2.9	4.3	0	−0.5	0.5	3.0
Large farms	−7.1	−2.9	−4.2	−5.1	−0.5	−4.6	0
Case 4[a]							
Small farms	−0.1	−2.7	1.6	−0.7	−0.2	−0.5	1.9
Large farms	−4.6	−2.5	−2.1	−3.4	−0.2	−1.4	0

[a] Parameter specifications are the same as for table 2.
[b] Assume $\delta = \delta_S = \delta_L = 0$.
[c] Assume $\delta = 0.4$, $\delta_S = 0.6$, and $\delta_L = 0$.

promoting a more equal distribution of income and welfare remains unchanged, even if the restrictive assumption of fixed home consumption by producers' households is removed.

Conclusion and Implications

The model and its application to the Philippine rice economy indicate that modern technology, such as the high-yielding rice varieties, benefits both consumers and producers. Within agriculture, it has an effect of promoting a more equal income distribution through downward pressure on prices and hence on the incomes of those farmers with a large proportion of marketed surplus. It tends to transfer income from large commercial farmers and landlords to the urban poor and the rural landless classes.

Between 1967 and 1970, when real rice prices fell by about 20% in the Philippines, the above forces were at work.[5] In more recent years, the supply function has not kept pace with the shifts in demand, resulting in sharp increases in rice prices. These increases have had an especially adverse impact on the level of living of low-income working classes. The rising prices have also provided large windfall gains to large producers who sell a major portion of their output, while providing little benefit to small semisubsistence farmers.

In fact, these phenomena represent the reverse of the results obtained in the model under the assumption of a rightward shift in the supply function with a stable demand function. In recent years the demand function has shifted faster than the supply function, resulting in sharp increases in staple food prices. In effect, technology has not shifted the supply curve fast enough. However, unless the supply function had been shifted by earlier developments in technology, the level of rice prices would have been higher, the increase might have occurred sooner, and the adverse effects of rising prices on income distribution would have been much greater.

The analysis suggests that a critical factor for attaining a more equal income distribution in the developing economies is the intensification of efforts for developing improved technology for the subsistence crop sector to enable the supply function of major food staples to shift more rapidly than the demand. However, this does not imply that technological advances can solve the whole problem. On the contrary, the data in tables 2 and 4 show that, if technical progress is slower for the small farmers than the large farmers, relative income gains for small farmers are reduced. A real danger would arise if new technology was monopolized by a small number of large producers, without causing a significant shift in the aggregate supply schedule. In such a case, the large farmers could capture the whole gain of technical progress by increasing output without a resulting decline in prices.

Likewise, if the large commercial farmers in a subsistence country exert their political power to have prices supported at the preinnovation level, then the benefits are captured

[5] Rice prices averaged 15.21 pesos per cavan (a measure of 44 kilograms) in 1967 and 14.95 pesos per cavan in 1970, while the consumer price index for areas outside Manila went from 106.2 to 129.7.

by those with a large marketed surplus at the expense of the taxpayers who bear the cost of price supports. (This does not occur with price stabilization programs designed to smooth out fluctuations within a year.)

It should also be reemphasized that this analysis abstracts from the possible changes in factor shares or factor ownership that might occur either as a result of technological change or at the same time but for independent reasons. The final impact of such changes on the income distribution would reflect the net effect of the new factor shares and factor ownership distribution, as well as the real income effects discussed above.

There are a number of conditions that might prevail in which the income distribution after the introduction of technological change might be more inequitable than the distribution before such an introduction. In order to avoid such a possibility, efforts should be strengthened to facilitate the adoption of technological innovations by small farmers. Improvements in public services for extension, credit, and marketing should be directed to this purpose. Especially critical is the provision of indivisible factors, such as irrigation, that may be too large for purchase by individual small farmers. However, all those efforts will not be effective in promoting a more equal income distribution in developing economies unless research and development are strengthened so that the rate of shift in the supply of the major subsistence crops can exceed the rate of shift in the demand for them.

Regional Differences in Agricultural Productivity in Selected Areas of India

K. William Easter, Martin E. Abel, and George Norton

Production functions are used to measure the contribution to agricultural output of infrastructure and the quantity and quality of traditional inputs. Measuring the contributions of inputs over time together with an assessment of their supply provide insights into the direction that agricultural development efforts should take in two regions of India. In the wheat region, continued increases in the quantity and quality of irrigation and improved crop varieties are promising sources of output growth. For the rice region, the development of rural roads and markets, increases in irrigation quality, and improved rice varieties are important sources of output growth.

Key words: agricultural productivity, India, regional differences, restraints, rice, wheat.

Earlier work by the authors strongly suggests that the restraints to changing the level and distribution of agricultural output vary among regions of a country (Abel and Easter, Easter 1972, Easter and Singh). Recent work by Herdt, De Datta, and Neely supports this view. Agricultural development efforts can be improved if the relevant restraints within agricultural regions of a country are properly identified and development programs are focused on removing them. Qualitative and quantitative differences in resource endowments among regions dictate different types of technological development as well as different development strategies.

The focus of this analysis is to measure, by use of production functions, the contribution to total output of not only the quantity of traditional inputs (land, labor, fertilizer, etc.) but also the quality of certain inputs, particularly irrigation, technology, environmental factors (soil types, rainfall, etc.), and infrastructure (transportation, markets, etc.). Identification and measurement of the contribution to output of different types of inputs together with assessments of their supply provide valuable insights into the direction that agricultural development efforts should take in different regions of a country. Certain factors affecting output, such as soils or climatic conditions, may be fixed, and production technology has to adjust to them. Other factors such as the quantity and quality of irrigation or infrastructural investments may have varying elasticities of supply. The possibility and cost of expanding the supply of such inputs may vary considerably among regions. Strategies for increasing agricultural output and productivity should incorporate the different factor supply responses among regions.

The analysis covers two regions in India. One, defined as the wheat region, comprises seventy-three districts in the states of Punjab, Haryana, Uttar Pradesh, Madhya Pradesh, and Rajasthan. These districts account for the bulk of total wheat production in India. The other region is the eastern rice region, consisting of sixty-nine districts in eastern Uttar Pradesh, Bihar, West Bengal, Orissa, and eastern Andhra Pradesh (Easter and Abel).[1] The unit of observation is the district. A list of

The authors wish to thank Vernon Eidman, Jean-Claude Koeune, Willis Peterson, Terry Roe, Peter Warr, and Ian Wills for their helpful comments. The authors are responsible for any remaining errors. Support for research on this paper was provided from an AID 211(d) Grant to the University of Minnesota.

[1] Assam is not included in the analysis because of the nonavailability of data.

the districts is contained in Easter, Abel, and Norton.

Data are available for a ten-year period, 1959–60 through 1968–69, for all of the districts for value of crop output, crop area, irrigation, and fertilizer. In addition, data for tractors and labor are obtained for the ten-year period by interpolating and extrapolating trends based on two census years.[2] (See appendix for sources for these data.) One would like to make use of the entire time series of cross-section data. However, trying to explain productivity differences among districts using only the above variables would undoubtedly lead to seriously biased estimates because (*a*) some of the above variables, such as land and irrigation, do not reflect variations in the quality of these inputs and (*b*) there are other factors specific to each district that are not reflected in the above data and for which time-series data do not exist.

A three-stage procedure is used to improve the specification of the estimated production functions. The first stage involves estimation of production functions from a ten-year time series of cross-section data using an error components model. This model allows calculation of regional effects for the districts that represent systematic variation in productivity levels among districts not explained by variations in the inputs used in the error components model. The calculated regional effects are summary measures of the effect on output of factors not included in the error components model. In the second stage, an attempt is made to explain variations in regional effects by a variety of factors not included in the original production function. Finally, production functions are estimated including these additional factors for 1959/60–1961/62 and 1967/68–1968/69 when data on more of the relevant variables are available. Only these latter estimates are reported in detail here. (Definitions of the variables used in the following sections are found in the appendix.)

Regional Effects

In analyzing a time series of cross-section data, one can employ an error components model to isolate effects that are specific to a region and relatively time invariant. (A more detailed discussion of the application of the error components model and the calculated regional effects is found in Easter, Abel, and Norton.) These effects are normally captured in either the error term or the coefficients of the nonregional specific variables in ordinary regressions applied to the total set of data. The error components model is discussed and applied by Balestra and Nerlove, Nerlove (1971a, b), Schultz (1969, 1973), and Mukhopadhyay.

The error components model is applied to both the wheat and rice regions using a time series of cross-section data in which crop output is regressed on crop area, irrigated area, fertilizer, tractors, and labor.[3] These independent variables explain 24% of the variation in the value of crop output in the wheat region and 31% in the rice region. For both the wheat and rice regions, the ranking of districts by the value of the calculated regional effects corresponds very closely to the ranking of districts by either output per hectare or by the importance of a district measured in terms of its contribution to total national production of either wheat or rice as calculated by Easter and by Easter and Abel.

The second stage involves regressing the estimated regional effects on a number of variables thought to be important determinants of productivity. In the wheat region, the quality of irrigation,[4] measured by either the tubewell or irrigation index variables, soil types, and rainfall are important explanatory variables.[5] These variables explain about 55% of the variation in the regional effects for the wheat region, with tubewells being the dominant explanatory variable. In the rice region, pumpsets,[6] soil types, rainfall, work animals,

[2] Data on other variables, such as work animals, can be derived from census data in a similar manner. However, use of these additional variables leads to serious problems of intercorrelation among several of the independent variables.

[3] An attempt is made to capture the effects of education by using literate and illiterate labor variables in place of total labor. However, literate and illiterate labor variables are very highly correlated, giving rise to serious problems of intercorrelation between these two independent variables.

[4] Farmers with tubewells have greater control over the timing of irrigation and the amount of water applied than do those using canal irrigation. We would expect tubewell irrigation to be more productive than canal irrigation.

[5] Several other variables are examined for the wheat region but are found to be statistically nonsignificant or so highly correlated with other independent variables as to result in statistically insignificant estimates of some of the coefficients. Work animals do not have a significant coefficient. Surfaced roads are not an important variable, probably because most of the wheat region had a reasonably well-developed system of roads during the period of analysis. A measure of research expenditures by district, developed by Evenson, is not significant. Finally, area planted to high-yielding varieties of wheat is insignificant because it is highly correlated with fertilizer and particularly tubewells.

[6] Most of the irrigation in the eastern rice region is surface

and surfaced roads are important variables.[7] These variables account for about 80% of the variation in the regional effects.

Productivity Analysis

The insights gained from the analysis of regional effects are used to formulate the production functions for the wheat and rice regions. It is not possible to utilize the ten-year time series of cross-section data because observations for the full period are not available for all the variables. Furthermore, estimation of data for some of these variables by interpolation and extrapolation from census data is undesirable because there is no reason to expect some variables to behave in a trend-like way and development of too many variables in this fashion results in serious problems of intercorrelation among independent variables. Consequently, the data used are three-year averages for the period 1959/60–1961/62 and two-year averages for 1967/68–1968/69. A two-year average is used for the latter period, since 1966–67 was an unusually dry year and data are not available for 1969–70. Weather conditions for the years employed are considered to be reasonably normal.

Wheat Region

Equations (1) through (4) in table 1 are for the 1959/60–1961/62 period. Equation (1) contains the five independent variables used in the error-components analysis. All of the coefficients are significant. The addition of work animals in equation (2) results in a significant but negative coefficient for labor.[8] This is due

irrigation. Easter (1974) has shown that the quality of surface irrigation systems is important in determining agricultural productivity. Unfortunately, data are not available to measure either variations in the quality of surface irrigation or in the number of tubewells. Instead, the number of pumpsets is used as a measure of the quality of irrigation.

[7] In contrast to the wheat region, surfaced roads are a highly significant variable. Two reasons explain this difference. First, traditional rice-growing areas are heavy rainfall areas, and it is difficult to transport inputs or products during the rainy season without adequate roads. Second, many parts of the eastern rice region have poorer roads compared with the wheat region.

[8] A measurement problem may exist with the labor variable. The variable represents the stock of labor available in each dis-

		(6.937)				(1.375)		
Constant	1.560	−0.216	−0.947	−0.813	0.546	0.108	1.481	1.522
$\bar{R}^2$	0.902	0.942	0.923	0.912	0.909	0.910	0.934	0.919

Note: *t*-values are in parentheses for the two-tailed test.

to the high intercorrelation between work animals and labor. Inclusion of work animals also increases the irrigated area and crop area coefficients. The addition of the soil dummy variables (of which black soils is significant), total rainfall, and tubewells has the effect of increasing the coefficient of crop area, reducing the size of the coefficients of irrigated area and fertilizer, and making the coefficient of labor negative but insignificant. The tubewell variable is correlated with both irrigated area and fertilizer, which may explain the decline in the size of the coefficients of these latter two variables in equation (3). To get around this problem, the irrigation index, a combined measure of irrigated area and quality of irrigation, is used in equation (4). This measure is statistically significant and results in a significant and larger coefficient for fertilizer than when tubewells and irrigated area are included as separate variables.

Similar analyses for the period 1967/68–1968/69 are contained in equations (5) through (8). The behavior of the coefficients in this set of equations with respect to alternative specifications is similar to that in equations (1) through (4). In this latter period the interaction between the fertilizer variable and the measures of irrigated area and irrigation quality are even more evident with the coefficients of the latter two variables being smaller and statistically insignificant in equation (7) compared with the other equations. In addition, the alluvial soils dummy becomes significantly positive in equation (8), indicating that alluvial soils become more productive relative to the other soil types with increases in irrigation, fertilizer use, and the associated use of new wheat varieties. The negative coefficient for total rainfall is due to the fact that irrigation has developed more rapidly in the drier parts of the wheat region.

A comparison of the results for 1959/60–1961/62 with those for 1967/68–1968/69 helps highlight some of the changes that have occurred. During this period there was a fairly rapid adoption of high-yielding varieties of wheat. By 1968–69, 48.5% of the total wheat area in the Punjab was planted to high-yielding varieties, 48.0% in Uttar Pradesh, 28.9% in Haryana, 16.4% in Rajasthan, and 2.7% in Madhya Pradesh (table 2). The districts comprising the wheat region fall within these five states. These adoption rates reflect a rather rapid rate of technological change.[9]

Comparing equations (3) and (7) and equations (4) and (8) in table 1, one sees that there are some rather sizable changes in the production coefficients associated with the introduction of the new varieties of wheat. The new technology has the effect of decreasing the coefficient of land, increasing the coefficients of tractors, labor, and tubewells, and decreasing the coefficients of fertilizer and irrigated area with both becoming insignificant in the latter period. When the irrigation index is used in place of tubewells, the coefficient of fertilizer remains significant, although the coefficient of the irrigation index itself is nonsignificant.

A Chow test is used to test if regressions (3) and (4) are significantly different from regressions (7) and (8), respectively. The calculated values of the F-statistic are 3.05 for the comparison of regressions (3) and (7) and 3.23 for the comparison of regressions (4) and (8). The hypothesis that the regressions are not different is rejected at the 1% level of significance for each comparison.

The calculated marginal products of the relevant independent variables corresponding to the equations in table 1 are given in table 3. Comparing the 1967/68–1968/69 period with 1959/60–1961/62, the following is observed. The marginal productivities of land, irrigated area, tubewells, and fertilizer decline, while

trict, not the amount of labor actually used. It may not be too unreasonable to assume that the difference between labor available and labor actually used is negatively related to output per hectare; i.e., high productivity districts make fuller use of available labor than low productivity districts. Such systematic measurement error would lead to a downward bias in the estimated labor coefficients.

[9] Area planted to high-yielding varieties of wheat is included as an independent variable in the 1967/68–1968/69 equations. However, because high-yielding varieties are highly correlated with fertilizer and irrigation, either the coefficient of varieties or the coefficients of fertilizer and irrigation are insignificant, depending upon the specification of the equations. The high-yielding varieties are, therefore, dropped, since of the three variables it is the only one that cannot be used in the early period.

Table 2. Percentage of Wheat Area Planted to High-Yielding Varieties by States, 1966–67 to 1968–69

State	1966–67	1967–68	1968–69
		%	
Haryana	1.8	12.0	28.9

Table 3. Marginal Products, Wheat Region

Independent Variable	1959/60–1961/62 Average				1967/68–1968/69 Average			
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
Crop area	0.185	0.219	0.323	0.308	0.172	0.184	0.217	0.170
Irrigated area	0.154	0.253	0.175	—	0.194	0.216	0.105	—
Fertilizer	58.27	57.64	46.37	61.40	4.81	5.01	2.50	5.35
Tractors	137.22	129.94	96.67	96.67	128.51	129.28	100.81	106.96
Labor	0.076	−0.155	−0.065	−0.059	0.151	0.058	0.104	0.141
Total rainfall	—	—	477.83	484.29	—	—	−95.06	−192.02
Tubewells	—	—	15,480.8	—	—	—	4,460.2	—
Irrigation index	—	—	—	0.207	—	—	—	0.197
Work animals	—	0.337	—	—	—	0.121	—	—

Note: Marginal products: change in the value of crop output in thousand rupees of a one-unit change in the independent variable. For example, according to equation (3), a one-hectare increase in crop area increases the value of output by 323 rupees (in terms of 1959/60–1961/62 average prices).

those for tractors increase slightly and those for labor increase substantially. The calculated changes in the marginal products are the results of both a change in technology and a change in the mean values of the independent variables, the two types of change reinforcing each other in some cases and offsetting each other in other cases. These two types of changes result in an increase in average crop output per district from Rs. 137.216 million for the 1959/60–1961/62 period to Rs. 161.600 million in the 1967/68–1968/69 period.

It is plausible to expect the new technology to lower the marginal product of land because it is land augmenting in nature. The geometric mean value of crop area per district also increases from 379,487 hectares to 405,889 hectares, which would *ceteris paribus* decrease the marginal product of land.

The new technology is dependent upon quality irrigation and fertilizer. It would not be unreasonable to expect the marginal products of both to increase. However, a decline is observed. The positive effect of technology on the marginal production may be more than offset by increased average use of these inputs. The geometric mean value per district of irrigated area increases from 52,561 hectares to 83,180 hectares, the irrigation index goes from 54 to 92, and the tubewell measure increases from 0.0039 to 0.025. The use of fertilizer increases dramatically from 219 metric tons per district to 2,387 metric tons. This increase reflects not only a higher productivity of fertilizer but a substantial decline in its price relative to the price of wheat. Over the study period the ratio of the wholesale price of wheat to the wholesale price of urea increases from 0.62 to 1.12, or by 80%.

While the new technology seems to increase the marginal productivity of tractors slightly, its effect on increasing the marginal productivity of labor appears to be substantial, even with an increase in average labor available per district from 273,758 to 282,095 workers.

Rice Region

The regression results for the rice region presented in table 4 are organized in a similar way to those for wheat in table 1.

One of the striking results in all equations is the insignificance of irrigation. Most irrigation systems in the rice region have little reservoir capacity and are heavily dependent upon rainfall and diverted stream flow. This may be the main reason why irrigated area yields nonsignificant results. The effect of irrigation is being picked up by the total rainfall variable, which is significant. June and October rainfall were tried in place of total rainfall, and these variables also had significant coefficients.

As mentioned earlier, data are not available on tubewells, so this form of irrigation could not be used in developing a measure of quality of irrigation. Data are available on pumpsets, and this measure had positive and significant coefficients for 1959/60–1961/62. Coefficients for pumpsets are negative but insignificant in 1967/68–1968/69. Separate analyses by Easter (1974) for parts of the eastern rice region show that improvement of the quality of irrigation increases production substantially. Better data on and measures of the quality of irrigation are needed.

The alluvial soils dummy is negative but statistically insignificant in both the 1959/60–

Note: *t*-values are in parentheses.

1961/62 and 1967/68–1968/69 periods in all but equations (6) and (7). The coefficients of the red-coastal alluvial soil are positive and significant in the 1959/60–1961/62 period but are positive and insignificant in the 1967/68–1968/69 period.

Surfaced roads appear to be important in explaining productivity differences among districts, and their importance increases in the latter period. The absence of roads in a heavy rainfall area such as the rice region has the effect of raising input prices paid by farmers and lowering output prices received by them due to higher transportation costs. As Easter and Singh point out, these price relationships are unfavorable to the use of modern inputs such as fertilizer, and they retard tubewell development, especially where electricity is not available and diesel fuel has to be used.

Fertilizer use makes a significant contribution to production. The availability and price of fertilizer and their relationship to infrastructural development (roads and marketing facilities) appear to be important considerations in increasing production in this region.

During the study periods there is little technological change, as measured by the adoption of high-yielding varieties, in the rice region, in contrast with what occurs in the wheat region. Data on the adoption of new varieties of rice are given in table 5. Of the states under study, Andhra Pradesh has the highest adoption rate in 1968/69, with 16.6% of the paddy area planted to high-yielding varieties. Accordingly, temporal changes in the coefficients of the production functions for rice as large as in those for wheat are not observed. Also, the change in the mean value of crop output per

Table 5. Percentage of Paddy Area Planted to High-Yielding Varieties by States, 1966–67 to 1968–69

State	1966–67	1967–68	1968–69
		–%–	
Andhra Pradesh	8.3	10.3	16.6
Bihar	1.5	4.9	5.0
Orissa	1.1	2.8	3.4
Uttar Pradesh	1.6	3.4	7.3
West Bengal	0.6	3.4	4.0

Source: Abel.

district is relatively small over the study period, from Rs. 200.845 million to Rs. 212.463 million.

A Chow test is used to test if regressions (3) and (7) and regressions (4) and (8), respectively, are different. The calculated values of the F-statistic are 1.88 for the comparison of regressions (3) and (7) and 1.57 for the comparison of regressions (4) and (8). The hypothesis that the regressions are not different cannot be rejected at the 5% level of significance for each comparison.

The calculated marginal products corresponding to the regressions in table 4 are presented in table 6. The marginal products for crop area, irrigated area, and tractors seem to increase slightly, those for surfaced roads increase substantially, the marginal products for fertilizer decline substantially, and those for labor decrease somewhat between 1959/60–1961/62 and 1967/68–1968/69. Over this same period the mean values of the variables per district go from 435,164 to 458,670 hectares for cropped area, from 42,951 to 60,951 hectares for irrigated area, from 374 to 2,014 metric tons for fertilizer, from 26 to 75 for tractors, from 540,365 to 534,988 for laborers, and from 124 to 194 for pumps.

The results are basically consistent with a slow rate of technical change and a decline in the price of fertilizer relative to rice. The ratio of the wholesale price of rice to the wholesale price of urea goes from 0.75 to 1.24, or an increase of 65% during the period being studied.

Conclusions

Factors other than traditional inputs unadjusted for quality differences are important in explaining agricultural productivity differences within and between the wheat and rice regions of India. Identification of these additional factors is important for sharpening the focus of planning and development efforts and increasing the productivity of development resources by directing them at easing the binding restraints to increased output.

For the wheat region in India, the introduction of new varieties, the expansion of irrigated area and improvement in the quality of irrigation through the use of tubewells, and increased supplies of fertilizer lead to substantial increases in production. In some parts of the wheat region, namely, the Gangetic Plain portions of central and eastern Uttar Pradesh, there is further opportunity to expand the area irrigated by tubewells (and canals). Further development of water resources in these areas will promote the adoption of the new wheat technology. In other areas, such as parts of Madhya Pradesh and Rajasthan, the opportunities for further irrigation are severely limited. The limitation of water will likely be an important restraint to adoption of new crop technologies requiring intensive use of water. Productivity increases in these areas will have to come from development and adoption of new technologies and production practices consistent with rainfed conditions.

In the eastern rice region somewhat different restraints appear to be binding during the period covered by this study. The development and adoption of improved varieties of rice are not widespread. Development efforts should be (and are being) directed toward the development of high-yielding varieties of rice adapted to local ecological conditions. Attention should also be paid to improving roads and related market structures in the eastern rice region. Development efforts along these lines would increase the profitability of new crop technology and the use of supporting in-

puts and speed their adoption. In separate analyses (Easter 1974), it has also been shown that there are very high social and private returns from improving the quality of canal irrigation systems. However, the government of India does not appear to give high priority to improving the quality of existing irrigation systems.

The usefulness of the foregoing analysis is illustrated by the work of Spriggs. Using data from table 4 together with other relevant information, he estimates benefit-cost ratios in the neighborhood of 8:1 for expanding the kilometers of surfaced roads in the eastern rice region, a handsome social rate of return, indeed. Furthermore, the assumptions used by Spriggs are purposely designed to yield conservative estimates of the calculated benefit-cost ratios. Similar analyses could be carried out with respect to other investment possibilities in each of the regions to determine the socially most productive investments.

In this approach we have tried to disaggregate the analysis of agricultural productivity growth using the district as the basic unit of observation. As in earlier work, we can combine these districts into relatively homogenous subregions with respect to the restraints to increasing output, although there still may exist much variation among the important constraints and the quality of factors within each subregion. Further disaggregation may be highly desirable to account for the remaining variability in productivity within regions and to identify better the binding constraints. The work by Herdt, De Datta, and Neely represents efforts in this direction and should provide valuable information for better directing development resources toward removing the overriding barriers to increasing agricultural productivity and improving the distribution of these productivity gains.

Appendix

Definition of Variables

Crop area: annual gross cultivated area (hectares) in each district (India, Government of 1970, 1971c).

Fertilizer: total metric tons of N, P, and K used annually in each district. This measure is an unweighted sum of the three nutrients (Donde and Brown).

Irrigation: annual gross irrigated area (hectares) in each district (India, Government of 1970, 1971c).

Irrigation index: calculated measure of gross irrigated area in each district in which area irrigated by tubewells receives a weight of 1.5 and all other irrigated area receives a weight of 1.0.

Labor: number of male and female agricultural workers in each district, including both cultivators and laborers. Data are available for the census years 1961 and 1971 and are derived by interpolation and extrapolation for other years (India, Government of 1961b, 1971b). This is a measure of the stock of agricultural labor available in each district but not of the labor actually employed in crop production.

Monthly rainfall: average rainfall for specified months, 1901–50, in millimeters, for each district (India, Government of 1962b).

Pumpsets: number of pumps including electric and oil engines used for irrigation. Data are available for only 1956, 1961, and 1966 (India, Government of 1956, 1961c, 1966).

Soils (rice region): three soil types are used—recent alluvial, red with coastal or deltic alluvium, and red. Districts are classified as described for soils in the wheat region. Dummy variables are used for recent alluvial and red with coastal or deltic alluvium (Rajan).

Soils (wheat region): three soil types are used—black, alluvial, and red. In general, a district is classified as belonging to a particular soil type if 50% or more of the land is accounted for by that soil type. Dummy variables are used for black and alluvial soils (Rajan).

Surfaced roads: kilometers of hard surfaced roads per square kilometer of land in each district. Data are available for 1968 for all states except West Bengal, where 1960 data has to be used (India, Government of 1961a, 1962a, 1969, 1969–70; West Bengal, Government of).

Total rainfall: average annual rainfall, 1901–50, in millimeters, for each district (India, Government of 1962b).

Tractors: number of tractors in each district. Data are available for 1956, 1961, and 1966 and are derived by interpolation and extrapolation for other years (India, Government of 1956, 1961c, 1966).

Tubewells: ratio of net crop area irrigated by tubewells to net crop area. Data are available for 1961 and 1968 (Punjab, Government of; Haryana, Government of; Rajasthan, Government of; Directorates of Agriculture, Madhya Pradesh and Uttar Pradesh). This variable as well as the irrigation index are used to measure differences in quality of irrigation.

Value of total crop output: annual total value of crop output in each district in terms of 1959/60–1961/62 average prices, in thousand rupees (India, Government of 1971a, c; 1970).

Work animals: number of work cattle and bullocks in each district. Data are available for 1956, 1961, and 1966 and are derived by interpolation and extrapolation for other years (India, Government of 1956, 1961c, 1966).

Labor Force Participation in Southern Rural Labor Markets

Loren C. Scott, Lewis H. Smith, and Brian Rungeling

Despite the extensive study of labor force participation rates, factors influencing the labor force status of rural workers have received relatively little attention. Employing primary data from interviews conducted in four southern rural counties, this study investigates the major determinants of labor force participation among six subgroups in the sample. Evidence from probit analysis indicates the critical role of health in the participation decision of virtually all subgroups. The expected wage is found to significantly influence the participation decision of secondary, but not primary, workers. Manpower policies involving day-care centers, discrimination, and job training are also investigated.

Key words: health, labor force participation, rural, South.

During the past decade a number of economists have studied the factors that determine whether or not a person participates in the labor force. The dependent variable in most of their models has been the labor force participation rate (LFPR) of some subgroup within the population (Barth; Bowen and Finegan; Cain 1969; Strand and Dernburg 1964, 1966; Wachter). These investigations sought to explain either variations in LFPR's across standard metropolitan statistical areas (in the cross-section studies) or variations in LFPR's of the national population over time. A smaller number of models have been based on observations across individuals, where the objective was to isolate those factors determining the labor force status (LFS) of the group involved. The dependent variable in these studies was dichotomous, taking on a value of one if the person was in the labor force and zero otherwise (Berkowitz and Johnson, Fleisher, Spencer, Gramm).

A common characteristic of these studies is their concentration either on urban populations or the total national population—the latter being 60% to 70% urban according to Marshall. None deals specifically with the participation decision of rural residents. The purpose of this paper is to complement these other studies by analyzing factors that determine the labor force status of the rural population and various subgroups within the population.

A comparison of LFPR's of rural residents versus the national population suggests that this is a fruitful area of inquiry. Table 1 illustrates these comparative rates across various race-sex categories. LFPR's across both race and sex lines are significantly lower for rural areas than for the national population. The figures in table 1 actually mask the magnitude of the differences because the rural data include only household heads and not all persons twenty years old and older.

A number of explanations for this rural-national variance are possible. It may be that the significant determinants of labor force participation differ between the two areas. Perhaps custom, tradition, and mores are sufficiently different in rural areas so that the marginal effects of the various determinants on the participation decision are stronger (or weaker). It is more likely, however, that factors detrimental to labor force participation —health problems, a population with a high dependency ratio, and similar factors—are quantitatively greater in rural areas. By estimating a model of rural labor force participation, these issues may be addressed, and manpower policies appropriate for rural areas can be suggested.

Loren C. Scott is an associate professor of economics, Louisiana State University; and Lewis H. Smith and Brian Rungeling are associate professors of economics, University of Mississippi.

This paper is part of a larger investigation of rural labor markets financed by a grant from the Employment and Training Administration, U.S. Department of Labor. The authors wish to thank Steve Farber, David Stevens, Randy Rice, Jim Richardson, and an anonymous referee for comments on an earlier draft. James Smith provided laudable computer assistance to the project. The authors are solely responsible for any remaining errors.

Table 1. Labor Force Participation Rates by Race and Sex, 1973

Subgroup	Labor Force Participation Rate	
	Rural[a]	National[b]
Men		
Anglos	69.2	81.6
Blacks	66.7	78.2
Chicanos	70.1	85.9
Women		
Anglos	32.6	43.5
Blacks	38.5	51.6
Chicanos	22.2	41.1

[a] LFPR's for rural residents come from our sample data and are for household heads only. National population rates are for women or men twenty years of age and older.

Data Source

Data used in this paper come from a household survey conducted in four southern rural counties in 1973. The counties were chosen from a sample of counties that have a majority of its population classified as rural, whose borders are more than 50 miles from a metropolitan area, and are within the Bureau of Census definition of the South. To be representative of the South, the counties ideally have a larger rural population and an economy historically dominated by agriculture. Four counties were selected in an effort to capture the rather wide range of socioeconomic characteristics of southern rural counties. The counties selected include a county in Texas located near the Mexico border whose population is almost totally Chicano, a Georgia county whose population is 75% Anglo; a Louisiana parish with a 60%-40% Anglo-Black population, and a Mississippi Delta county with a 40%-60% Anglo-Black racial mix. The Mississippi, Louisiana, and Texas counties have work forces that are heavily oriented toward agriculture. There is a large migrant worker contingent whose permanent base is in the Texas county. The Georgia county is the most industrialized of the four.[1]

Data were collected in the counties by personal interview from a random sample of 3,357 households. The sample was selected from a list of addresses with location of all dwelling units updated from 1970 census records (U.S. Dep. Commerce 1973), by aerial photographs (U.S. Soil Conservation Service), and data supplied by local authorities (Dep. Highways Office). A simple random sample was drawn from the list of households.

Data were collected and broadly classified into several groups: (*a*) demographic information; (*b*) labor force information, both historical and current; (*c*) income and earnings and physical asset data; (*d*) welfare program information; and (*e*) behavioral and attitudinal information. The sample of 3,357 households provides a wide variety of labor market data on 7,481 individuals over sixteen years of age.

The Labor Force Status Model

In an attempt to isolate those factors that determine whether or not a rural resident participates in the labor force, a labor force status model is developed and estimated for seven subgroups of the rural population. These seven subgroups can be separated into two classifications—primary workers and secondary workers. Primary workers include household heads inclusively, prime-age males (ages 25 to 54), and female household heads. Four subsets of secondary workers are examined—elderly males (ages 65 and up), married women, teenage males, and teenage females.[2] These particular secondary workers are chosen because their national LFPR's have been experiencing rather dramatic changes since the turn of the century.

The basic LFS model is

$$(1)\quad LFS = f(WED, HEALTH, OINCOME, EWAGE),$$

where *LFS* is a dichotomous dependent variable taking on a value of one if the individual is participating in the labor market and zero otherwise. Because *LFS* is dichotomous, the ordinary least squares (OLS) regression technique for estimating equation (1) is inappropriate, since such a dependent variable would introduce heteroskedasticity into the error term. As a result, the variances of the coefficients in an OLS equation would be biased in a direction that may lead to rejection of some coefficients that may, in fact, be statistically

[1] Unpublished 1974 data from the Bureau of Economic Analysis show that total labor and proprietor's income in the farm sector in the Mississippi, Texas, Louisiana, and Georgia counties were (in millions) $40.9, $21.7, $14.1, and $7.9, respectively (U.S. Dep. Commerce 1970–74).

[2] By definition, the married women and teenage subgroups do not contain any household heads.

significant. Also, the resulting estimate of the conditional probability of participation is not constrained to fall within the zero to one range (see Kmenta, pp. 425–28). Several methods of data transformation are available for correcting this problem. The probit technique developed by Finney is chosen to estimate equation (1).

Equation (1) suggests that the decision to participate in the labor force is influenced by the marital status of the individual (*WED* = 1 if married; 0 otherwise). Those persons who are married have greater financial responsibilities than those who are single; thus, the former are more likely to be in the labor force than the latter (see Bowen and Finegan, p. 23).

Mushkin has shown that health problems are detrimental to labor force participation, and investigations based on urban and national samples have supported this hypothesis empirically (Davis; Luft; Morgan, David, and Brazer). Individuals in the rural sample were asked a series of questions relating to health, including the nature of their health problem, whether or not the individual was under a doctor's care, the time elapsed since the health problem was first discovered, and the anticipated duration of the problem. The individual was asked if he believed the problem impaired his ability to work. The total acquired information was analyzed to determine if an individual had a health problem that could affect his work performance. *HEALTH* in equation (1) is a dummy variable with a value of one for those who were determined to have a work-inhibiting health problem and zero for all others.

Work-leisure indifference curve analysis suggests that the receipt of nonlabor income should cause an individual to choose more leisure time (assuming leisure time is a normal good) and to work less. To control for differences in the amount of nonlabor income received across individuals, *OINCOME*, defined as the difference between total household income and earnings of individual, is included in equation (1).[3] Although the components that other income should include as well as the nature and strength of its impact on the LFS of different groups has not been unequivocally established, the need for some measure of other income in the LFS analysis is generally recognized (see, for example, Berkowitz and Johnson; Bowen and Finegan; Luft; Morgan, David, and Brazer; Wachter). Recent findings by Watts et al. indicating that the disincentives associated with outside income are greatest for low income families are of particular relevance to this study.

Two additional variables are employed in the LFS equations for women. Since women have traditionally assumed responsibility for the care of children in the home, the presence of children should have a negative influence on the woman's decision to enter the labor force. The presence of children in the home in effect raises the woman's "at-home wage" and induces her to remain out of the labor force. Hence, the variable *CHILD* (1 = has responsibility for children at home; 0 otherwise) is added to the LFS equations involving women. Cain (1971) has shown the presence of child-care facilities nearby can reduce some of the costs of child care and induce some women to enter the labor force at the margin. Thus, *CARE* (1 = child-care facilities available nearby; 0 otherwise) is also added to these equations. A modification is also required in the LFS equations for teenagers to allow for an obvious and important alternative to work for them—school attendance. *SCHOOL* (1 = presently attends school; 0 otherwise) is used to capture this effect.

Finally, *EWAGE* in equation (1) is the expected wage rate per hour of the individual if employed. Following Bowen and Finegan, one would think that the greater the *EWAGE*, *ceteris paribus*, the greater the individual's inducement to substitute an incremental hour in the labor market for an incremental hour at home. A difficult practical problem is how to measure *EWAGE*. Actual wage data are available only for those persons presently employed. In the LFS model, an expected wage must be inserted for all three classifications of individuals: those who are working (*E*), those who are actively seeking work (*U*), and those who are out of the labor force (*O*). One approach might be to use the actual wage of the *E*'s for their *EWAGE* and then employ an average wage of the *E*'s as estimates of *EWAGE* for those classified as *U* or *O*. However, not only does the mixture of an actual wage and an expected wage in the empirical estimation present theoretically difficult prob-

[3] *OINCOME* includes primarily government transfer payments and earnings of other household members. A very small component comes from private transfers. No in-kind income is included, nor are food stamps. Although the food stamp bonus represents income, for a significant percentage of the sample households the purchase requirement prevents the incorporation into the *OINCOME* variable in any meaningful way; that is, it represents a decline in actual food prices subject to a constraint and is unlikely to be recognized as an increase in income.

lems but imprecise results also arise because the only persons with values below the mean wage are those currently employed, an unlikely depiction of reality.

Rather than mix actual and expected wages in the model, a methodological approach previously taken by Boskin is chosen that uses an expected wage across all individuals in the sample. The following model is derived in order to determine a person's *EWAGE:*

(2) $EWAGE = f(SEX, ANGLO, BLACK, AGE, AGESQ, ED, TRAIN, GA, MISS, LA)$.

A person's expected wage is dependent on several factors in the labor market. Marginal productivity theory suggests that those persons with more education, formal training, and job experience, i.e., with greater endowments of human capital, are expected to earn higher wage rates. Hence, *ED* is entered as a continuous variable measuring years of education attained via elementary school, secondary school, and college. *TRAIN* is a dummy variable taking on a value of one if the person participated in a formal vocational or on-the-job training program, such as offered through Concentrated Employment Programs, Work Incentive Programs, and Manpower Development and Training Act programs, and zero otherwise. Serving as proxies for amount of on-the-job work experience are *AGE* and *AGESQ*—the individual's age (in continuous form) and age squared.

Equation (2) contains three variables designed to capture differentials in expected hourly wage rates across sex and race lines. *SEX* is a dichotomous variable having a value of one for men and zero for women. The rather voluminous literature on sex wage differentials indicates that *SEX* should be positively associated with *EWAGE* either because women suffer from wage discrimination (Ferber and Lowry) or their occupational choices, considered alongside household duties, lead them into lower paying jobs vis-à-vis men (Gwartney and Stroup). Racial wage differentials are measured by using *ANGLO* (1 = anglo; 0 = nonanglo) and *BLACK* (1 = black; 0 = nonblack). The omitted category is Chicano; hence, the coefficients on *ANGLO* and *BLACK* measure anglo and black wage rates relative to those of Chicanos. While it is not clear what sign should be expected on the *BLACK* coefficient, the coefficient on *ANGLO* should be positive, reflecting racial discrimination and/or differences in the quality and quantity of education and training received by nonwhites vis-à-vis whites.

Differences in the economic health and general job availability between the four counties in the sample may influence the general wage rates received by residents of one county when compared with another. To hold constant these variances across counties, *GA* (1 = resides in the Georgia county; 0 otherwise), *MISS* (1 = resides in the Mississippi county; 0 otherwise), and *LA* (1 = resides in the Louisiana parish; 0 otherwise) are inserted in equation (2). Thus, the coefficients on each of the county variables measure how wage rates in that county compare with the Texas county, which is the one omitted.

Equation (2) is estimated using as observations the rural residents who are employed. Once estimated, both employed and nonemployed persons' characteristics are inserted into equation (2), and the individual values for *EWAGE* are established for use in the LFS equation. To the extent that the independent variables in equation (2) significantly affect *EWAGE,* they also indirectly affect the LFS decision in those subgroup LFS equations where *EWAGE* is significant.

Empirical Results

The EWAGE Equation

In table 2 the results of estimating equation (2) are presented. All of the signs are in the direction suggested by a priori reasoning. Each of the human capital embodiment variables—labor market experience (via *AGE, AGESQ*), education, and formal training—is significantly related to *EWAGE*. In addition, the results indicate that men earn significantly more per hour than women after adjusting for human capital differences. There is the problem of determining whether the lower wages earned by women are the result of employer discrimination or occupational preferences of women. Another study using a national sample suggests that national male-female wage differentials are more a function of female occupational preferences than sex discrimination (Gwartney and Stroup). It is argued that because women have, in addition to possible market-work responsibilities, responsibility for housework and child care, they choose

those types of jobs that involve low pay but that have work schedules that allow them to also perform their housework. While the data do not permit a direct resolution of this issue, they do reveal substantial occupational segregation on the basis of sex, as well as other evidence of wage discrimination.[4]

The issue of racial wage differentials in these southern rural counties is less clear. The *t*-value on neither race variable is exceptionally high. However, the *t*-value on *BLACK* (1.91) is sufficiently large so that a notable racial wage differential—adverse to blacks—is implied. Because human capital differences were held constant, there is a strong presumption that the racial wage differential is due to discrimination. One might argue that the education variable is not adjusted for differences in the quality of education received across race lines, which at least one study found to be a significant factor in the black-white differential (Welch). However, the educational quality differential may also be a product of past discriminatory behavior. Thus, to the extent that *EWAGE* significantly influences the LFS decision, wage discrimination toward blacks adversely affects their labor force participation in southern rural markets.

Finally, it is pointed out above that the four counties in the sample have varying industrial mixes. Once racial, sex, and human capital differences have been controlled, the statistics for *GA*, *MISS*, and *LA* suggest that these proxies for variations in industrial mix, the level of economic activity, and job availability between counties have no significant influence in *EWAGE*.

The LFS Equation

The ultimate objective of this research is to discover those factors that determine whether or not a rural resident will participate in the labor force. Table 3 contains selected characteristics of the sample subgroups, and the culmination of this inquiry is presented in table 4.

Perhaps the most consistent phenomenon in

[4] When differences in productivity factors are held constant, the average male wage remains over 40% higher than the female wage. For a more complete discussion of sex discrimination, see Smith, Smith, and Rungeling.

table 4 is the importance of health in the labor force participation decision of the rural population. The only equation in which health is shown to have no significant affect on the desire to work is the teenage women equation. Table 3 shows that only 3% of this subgroup indicated having health problems severe enough to prevent holding a job. The importance of health in explaining labor force participation is evident in the findings of investigations of urban and national LFS decisions (Davis; Luft; Morgan, David, and Brazer). Interpretation of the results requires qualification. Although a priori reasoning, casual observation, and intuitive feeling strongly suggest that the labor force status of the individual is affected by his health, researchers have noted correctly that there is a substantial amount of interaction between such factors as health and education and labor force participation (Bowen and Finegan, Davis, Luft). Therefore, such variables could serve as surrogates for a measure of health. Berkowitz and Johnson, however, demonstrated that for their sample neither education, other income, nor marital status is a proxy for health and that the omission of measures of health reduces the explanatory power of analytical labor force participation models.

It is possible in the present study that the health variable may in part reflect the narrower industrial structure in rural areas. Unlike metropolitan areas, the economy of the rural South contains few jobs that are accessible to persons with severe health problems or physical handicaps. It is possible that a significant number of rural persons outside the labor force due to health problems would in fact be employable in urban areas.[5]

EWAGE has the expected positive influence on the LFS decision and is statistically significant in all the equations except that for prime-age males. As one might predict, the coefficient on *EWAGE* is larger for secondary workers than for primary workers. Secondary workers typically have greater freedom in choosing between participation and nonparticipation in the labor force. Married women, for example, with their presumed responsibility for child care and housework, are more likely to be drawn into the labor force by higher wages. Prime-age males, on the other hand, whose chief responsibility is that of breadwinner, have less freedom of choice in the LFS decision and are more prone to work no matter what the *EWAGE*.

Income from sources other than the job has

[5] One test of this hypothesis might be to estimate equations (1) and (2) for a comparable group of urbanites. If the coefficient on the health variable indicates a significantly larger negative impact on the LFS decision in the rural equation than in the urban one, this constitutes evidence in support of the hypothesis. Unfortunately, no urban data were collected in this study, and the models used in other investigation are not sufficiently comparable with ours to make direct comparisons.

the expected negative relationship with the LFS decision of all adult subgroups in the sample. While there is a question of direction of causality, work-leisure indifference curve analysis argues that increases in positive income transfers—such as welfare payments, social security—should reduce the labor force participation of adult recipients. However, given that *OINCOME* is entered in thousands of dollars, the magnitude of its coefficient suggests that the marginal influence of these payments on the LFS decision is probably rather minor, particularly when compared with *HEALTH* and *EWAGE*. As a result it can be anticipated that increased labor force participation by secondary workers would not have a noticeable effect on the labor force status of primary workers.

Responsibility for children in the home has an expected detrimental effect on the participation decision of married women and teenage women. However, responsibility for children appears to encourage female household heads to enter the work force. Possibly, this is because these latter women are unmarried, and the *CHILD* variable has the same influence on their LFS decision as the expected influence of *WED* on the male LFS decision; that is, the increased financial responsibilities imposed by the children exert a pressure on female household heads to enter the labor force. From a manpower policy standpoint, it is interesting to find that the provision of nearby day-care centers draws adult women into the labor force, with the influence being particularly strong for female household heads.

Finally, it is no startling revelation to find that the LFS decision of rural male teenagers is strongly influenced by whether or not they are in school. Thus, manpower policies designed to improve the educational attainment of this group result in conflicting effects on the teenage male LFPR. On the one hand, more education tends to directly draw him out of the labor force. However, the higher educational level improves the teenager's *EWAGE*, which tends to draw him into the labor force.

Summary and Implications

That the incidence of poverty is greater in rural areas than in urban areas is well documented by Marshall.[6] One aspect of this rural-urban poverty differential is the lower labor force participation rates of rural residents. By examining the determinants of labor force participation rates among this segment of the population, we have been able to isolate a number of areas where manpower policies might be fruitfully applied to improve this dilemma.

For example, since *EWAGE* has a significant and positive impact on the LFS decision of six of the subgroups examined, manpower policies that might raise *EWAGE* should indirectly increase the LFPR of the rural population. For example, these results show that the *EWAGE* is positively associated with educational attainment and participation in formal training programs. Thus, manpower policies that reduce drop-out rates, increase the quality of education, and/or allow greater enrollment in government-sponsored training programs should have the beneficial by-product of improving rural LFPR's, particularly for secondary workers. This finding could hold significant implications for anti-poverty efforts in the rural South. Many households surveyed in this study were above the poverty level only by virtue of the earnings of secondary workers. In addition, many more would have been lifted beyond the poverty threshold if there had been a secondary worker in the household.

Further, to the extent that sex-wage differentials are due to sex discrimination (rather than occupational preference on the part of women), manpower policies designed to reduce this phenomenon will indirectly lead to greater rural LFPR's. This evidence also suggests a "borderline" relationship between *RACE* and *EWAGE*. Consequently, it is quite likely that efforts to improve the quality of education received by blacks and to remove any overt racial discrimination towards them will not only improve the *EWAGE* for blacks but may also increase their LFPR.

That poor health is a major factor inhibiting labor force participation in the rural South is quite evident from the data. Of the sixteen- to sixty-five-year olds with health problems in this sample, only 25% are participating in the labor force. The most numerous type of health problems are those classified as cardiovascular, followed in order of incidence by arthritis, mental and nervous disorders, and vision and hearing problems, The percentage of persons

[6] In 1970, in the South, the median income of urban residents was $3,814, while the comparable figures for rural farm workers was $2,700 and for rural nonfarm workers it was $3,130 (Marshall, p. 77).

with these problems who are unable to participate in the labor force are 19.8%, 28.0%, 11.9%, and 30.0%, respectively.

Perhaps a large part of this strong impact of health problems on labor force participation results from the disadvantages faced by rural areas vis-à-vis other areas in the provision of health care. While the number of hospital beds per 1,000 population was 7.4 nationally in 1971, the figure ranged from 1.2 to 5.1 in the counties in this sample. Similarly, the number of persons per doctor ranged from three-and-one-half to over seven times the national average for these rural counties (see Hague; U.S. Dep. Health, Education, and Welfare). Although there is little data to support the contention, there is a strong presumption that the quality of health services in rural areas is not on a par with those in urban areas. Since health services are thought to be income elastic, and because incomes are lower in rural areas than in urban areas, it is most unlikely that market forces alone can be relied on to remove the disparity. If improvement of LFPR's in rural areas is to be a national manpower objective, these findings suggest that additional public funds for health services and preventive health care in rural areas may be beneficial. It appears to be true that, although nonparticipation by certain groups (especially prime-age males) is not exclusively a medical problem, increased access to health care should increase labor force participation (Bowen and Finegan). Furthermore, health services or preventive health care surely provide social benefits greater than the output loss attributed to the afflicted.

Based on the evidence from this sample, we have suggested manpower policies that should increase the number of individuals desiring work in rural areas. However, to effectively combat poverty in these regions, policies designed to raise rural LFPR's must be combined with programs that will also create jobs. Without the latter, the former will merely create additional frustration and social unrest.

Public Service Employment and Rural America

Philip L. Martin

Public service employment programs are manpower instruments that provide income and transitional employment in times of high unemployment. Despite annual expenditures of nearly $1 billion since 1971, little attention has been directed toward the rural-urban distribution of public employment funds. After establishing alternative allocation formulae, actual allocations are compared with hypothetical allocations for public employment programs since 1971. The results indicate that rural areas did not obtain public employment funds in proportion to their shares of total unemployment. Reasons for the observed pattern of allocations are explored, and alternative allocating criteria to increase funds available to rural areas are discussed.

Key words: manpower programs, public employment programs, rural areas, unemployment.

In 1971, the nation initiated a national public service employment (PSE) program to help mitigate the individual hardships attending severe unemployment and to enable state and local governments to supply needed public services. First under the Emergency Employment Act (EEA) of 1971 and later under titles II and VI of the Comprehensive Employment and Training Act (CETA) of 1973, federal outlays for this countercyclical labor market instrument have averaged nearly $1 billion annually. At the estimated $8,000 cost per man-year of public employment, the $1 billion outlay provided only 125,000 jobs for the 5 million unemployed in 1974. Thus, to distribute the limited funds available for combatting unemployment via public service employment, allocation formulae had to be devised for disbursing available funds among states and local areas.

This study examines the rural-urban distribution of funds for the creation of public service employment programs since 1971. Under the EEA, county census data (U.S. Dep. Commerce) are aggregated to construct indicators of need for a ten-way county class taxonomy in which all counties or county attributions are arrayed along a rural-urban spectrum. Ratios derived by comparing county class shares of PSE monies with various indicators of county class need shares are constructed to assess the equity of the actual allocations process. Under the CETA, the same funds-to-needs share ratios are derived for states and prime sponsoring agents within states. Although none of the alternate need indicators are a perfect measure of relative area funding priorities, the indicators used should produce ratios of funding shares to need shares that are close to but not uniformly one.

The following section epitomizes the salient provisions of the EEA and the CETA. After describing fund allocation procedures and program administrative requirements, actual fund distribution patterns under the EEA and the CETA are reviewed. The sources of the observed rural bias are hypothesized to emanate from (*a*) the allocation criteria utilized, especially from reliance on local unemployment estimates; (*b*) administrative requirements that limit outlays for ancillary equipment; and (*c*) rural-urban differences in program outcomes, i.e., the ability of the program to reduce unemployment. Because federal outlays for programs that explicitly seek to reduce unemployment dominate any state and local efforts, modifications of prevailing allocation formulae that could redress appar-

Giannini Foundation Research Paper No. 436. The author is indebted to Lee Bawden, Robert Coltrane, and the editor for helpful comments on an earlier version of this paper.

ent discrimination against rural America are noted in the conclusion.

Public Service Employment Programs

Public service employment programs are manpower instruments designed to provide income, transitional employment, and needed public services, generally in times of high unemployment. First implemented on a national scale during the depression years, more recent PSE programs have been broadened to emphasize both countercyclical and work experience goals. The countercyclical goal of PSE's is essentially that of a work-conditioned unemployment insurance scheme. The work experience goal aims to simultaneously lower unemployment rates among specific target groups (Viet Nam veterans, minority unemployed persons, and low-income household heads) as it provides opportunities to train participants for entry into regular public employment, i.e., to make the transition from unemployed to regular employment status. Because need far exceeds total PSE appropriations and certain persons and/or areas are assumed to suffer most from unemployment, allocation formulae must be devised to distribute funds among competing target groups and/or areas.

Under the EEA and the CETA, allocations are made on the basis of a formula that gives equal weight to the volume and severity of area unemployment (the target groups specified in the enabling legislation act to determine local hiring priorities). Under the EEA, 75% of available funds are allocated to areas in proportion to their shares of national employment and their shares of national unemployment in excess of 4.5%. The remaining 25% of EEA funds are disbursed to areas whose unemployment rates for three consecutive months are in excess of 6%. An area's total EEA appropriation represents the sum of a volume and a severity of unemployment appropriation. Under the EEA, each state is guaranteed at least $1.5 million annually, and each program agent, who actually expends funds, is required to make a 10% contribution to the local appropriation.

The Comprehensive Employment and Training Act (CETA) emerged in late 1973 when political disagreement resulted in the expiration of the EEA. Of CETA's six titles, two appropriate funds for the creation of public service employment jobs.[1] Under title II, PSE funds are apportioned among areas experiencing unemployment rates in excess of 4.5% in accordance with area shares of unemployment, while title VI disburses funds according to a three-part formula that weights the area's share of total unemployment, the area's share of unemployment in excess of 4.5%, and the area's share of total unemployment in excess of 6.5% at one-half, one-fourth, and one-fourth, respectively. Under CETA, the local contribution requirements and state appropriation guarantees are dropped.

After determining a state's total allocation, PSE funds are apportioned to two types of areas within a state—direct prime sponsoring units of government, representing at least 75,000 persons under the EEA (100,000 under CETA), and smaller governmental units, which become subagents under each state's balance-of-state program. Prime sponsors or program agents, the larger cities and counties,[2] deal directly with federal allocating authorities (the regional manpower administrators), while state subagents seek funds through their state government. States are free to use any "equitable" formula for allocating funds among subagents in balance-of-state areas.

PSE Allocations Under the EEA and the CETA

In order to appraise PSE program allocations, the actual distribution must be compared with some alternative distribution. In this analysis, the share of PSE funds accruing to each county (EEA) or each state (CETA) is compared with the county or state's share of total unemployment or some other need indicator.[3]

---

[1] Title I funds, the largest expenditure component under the CETA, support comprehensive manpower services in local areas. Although title I funds can be used to fund public service employment, the crossover is limited. In fiscal 1974, only 5% of title I funds were diverted from manpower services to public service employment. Titles III through V deal with special groups and policies. Title III directs the secretary of labor to operate manpower programs for youth, offenders, Indians, migrant farmworkers, and the underemployed. Title IV continues the Job Corps, and Title V establishes a national commission for manpower policy. Title IV was passed in December 1974 as the Emergency Jobs and Unemployment Assistance Act.

[2] In addition to states and the larger governmental units, Indian tribes and areas of "exceptional circumstance" may be designated as direct prime sponsors without regard to the population criterion.

[3] The allocation criteria suggested are those that were most prominent in congressional debate before the program's enactment, the unemployment share argument being concerned with

If the resulting ratio is one, the county or state receives a share of funds commensurate with its share of unemployment (or other indicator of need). Ratios greater than one indicate overallocations under the actual allocation formula, while ratios less than one indicate underallocations; i.e., had allocations been made according to unemployment shares, the area would have received more funds. Since evidence on shares of severe unemployment is not always available by county and state, one would expect a distribution of funds-to-unemployment share ratios close to but not uniformly one.

Under the EEA, allocations to counties for both unemployment shares and severities are tabulated according to a county taxonomy that arrays the 3,100 U.S. counties along a ten-way rural-urban spectrum (Hines, Brown, and Zimmer). For each county class and for the metropolitan-nonmetropolitan aggregates, the ratio of the share of funds to the 1970 unemployment share is calculated by county class (table 1). It is immediately apparent that nonmetropolitan areas did not receive funding shares commensurate with their shares of unemployment; indeed, the most rural counties fared worst. The fiscal year (FY)1973 distribution pattern, for which 1970 unemployment shares are a less reliable alternative allocator, shows the nonmetropolitan county classes improving their position but still receiving only 39% of the funds due them compared with their expected allocations under an unemployment shares criterion.[4]

While metropolitan counties, containing 72.8% of the unemployed, received nearly 90% of EEA funds in FY 1972 (88% in FY 1973), nonmetropolitan counties, with 27.2% of the unemployed, received only 10% of EEA funds (12% in FY 1973). Among nonmetropolitan counties, allocations range from 5% to 108% of a county class's unemployment-mandated share of funds, e.g., class 9 nonmetropolitan counties contained 1.11% of all unemployed persons but received only 0.06% of the EEA funds in FY 1973. In both FY 1972 and FY 1973, and under both the EEA and the CETA, the four county classes containing less than

restoring full employment and the population share proponents citing the lack of detailed unemployment data.

[4] The CETA data at the county level (Office of Economic Opportunity) are not strictly comparable with EEA allocations, since they include allocations for general manpower programs as well as public service employment.

Table 1. Population and Unemployment Distributions and EEA and CETA Funding Shares, Metropolitan and Nonmetropolitan Counties

County Class[a]	Unemployment Share, 1970[b]	Population Share, 1973[b]	Fund Share/ Unemployment Share[c] EEA, FY 72[d]	EEA, FY 73[d]	CETA, FY 74[d]	Fund Share/ Population Share[e] EEA, FY 72	EEA, FY 73	CETA, FY 74
	----%----							
Metropolitan (612)	72.80	72.55	1.25	1.23	1.15	1.25	1.23	1.16
Core (48)	32.60	28.26	1.48	1.36	1.20	1.70	1.57	1.39

Thinly populated nonadjacent (626)	2.08	2.17	0.14	0.10	0.50	0.14	0.09	0.48

[a] The county classification is explained in Hines, Brown, and Zimmer. The number of counties in each class is in parentheses. The county classes are based on population density and proximity to SMSA's.
[b] Unemployment and population shares are derived from U.S. Dep. Commerce.
[c] The fund share/unemployment share ratio is calculated by dividing the share of total funds allocated to the respective county classes by the percentage of the nation's unemployed residing in the respective county classes in 1970.
[d] Fund shares are derived from *Federal Outlays* (Office of Economic Opportunity).
[e] The fund share/population share ratio is calculated by dividing the share of total funds allocated to the respective county classes by the percentage of the nation's population residing in the respective county classes in 1973.

20,000 urban residents received the least funds, irrespective of their contiguity to a standard metropolitan statistical area (SMSA). Among metropolitan counties, core central city areas were uniformly favored, with only the fringe counties adjacent to large SMSA's, i.e., the suburbs, not receiving their unemployment-mandated funding shares.

County level unemployment data are available only in census years; hence, comparison of 1970 unemployment shares with subsequent funds shares loses credibility over time. But the general picture of underallocations to rural areas that emerges from FY 1972 funds-to-unemployment share ratios seems to hold for subsequent years, since funds-to-population shares, which can be updated annually, are strikingly similar for the years when both unemployment and population data exist. In FY 1972, when nonmetropolitan counties contained exactly the same proportions of total unemployment and total population (27.2%), both the unemployment and population share analysis indicate that nonmetropolitan counties obtained only 34% of their justified allocation (table 1). Furthermore, the ratios computed from unemployment and population shares are remarkably similar over time, especially at the aggregate metropolitan-nonmetropolitan level, which suggests that relative unemployment shares remained stable over time.[5]

The EEA is designed to provide "transitional employment for unemployed and underemployed persons" (U.S. Congress, Senate). Because no precise definition of underemployment has emerged, no underemployment data enter the PSE allocation formula. The incidence of those factors cited as indicative of underemployment, viz, low-income household heads, involuntary part-time workers, and discouraged workers, is at least as frequent in rural as in urban America (Horne, Tweeten, and Holland; Marshall, p. 81). If, for example, funds are allocated on the basis of county class shares of low-income household heads, the apparent funding bias against rural areas would increase, with nonmetropolitan counties decreasing their share of total PSE funds from 34% of unemployment-indicated need to less than one-fourth of their "underemployment" deserved share of funds.

Under the CETA, county level PSE allocation data are unavailable for all states. Calculation of the same funds-to-unemployment share ratios at the state level produces a wide disparity in funds-to-need share ratios across states. Under both titles II and VI, those states that received less than 50% of the funds due them on an unemployment-share basis trace a U-shaped pattern from the upper Midwest across the South and along the southern coastal plain (figure 1). The source of this peculiar regional bias is not immediately obvious, although it should be noted that (*a*) the South experienced increased unemployment relatively late in the recession (Gellner, p. 15); (*b*) most of the states having low funds-to-unemployment share ratios are of intermediate population size, suggesting the possible existence of both small state and large state biases; and (*c*) some states and local areas may have failed to apply for PSE program funds.

After determining allocations to individual states, PSE funds are allocated to prime sponsors within each state, with each state acting as a prime sponsor for its rural or nonmetropolitan areas. Diversity among states precludes ready generalization, but apparently states that are underallocated funds in accordance with their shares of national unemployment in turn concentrate the PSE monies they received in their dominant urban areas. Unpublished data collected by the Regional Manpower Administration show that Kansas and Nebraska, for example, receiving only 10% and 40% of the PSE funds expected given their shares of total unemployment, in turn devote 25% and 96% of PSE funds received under title II to Kansas City and Omaha, respectively. Thus, even if states currently underallocated funds under existent PSE programs are to receive their unemployment-mandated funding shares, there is no assurance that these states would pass on such funds to their rural balance-of-state areas.

Sources of Rural Bias

The distribution of funds for the creation of public service employment programs under both the EEA and the CETA exhibits strong biases in favor of urban areas. Rural areas could fail to qualify for PSE funds if (*a*) their need for funds is underestimated; (*b*) the tim-

[5] Total unemployment rose some 22% (on an average annual basis) between 1970 and 1971 (U.S. Dep. Labor 1975). Since nonmetropolitan counties had higher unemployment rates in 1970, even if all the increase in unemployment between 1970 and 1971 was concentrated in metropolitan counties, a funds-to-unemployment share allocation would have provided more PSE funds to nonmetropolitan counties.

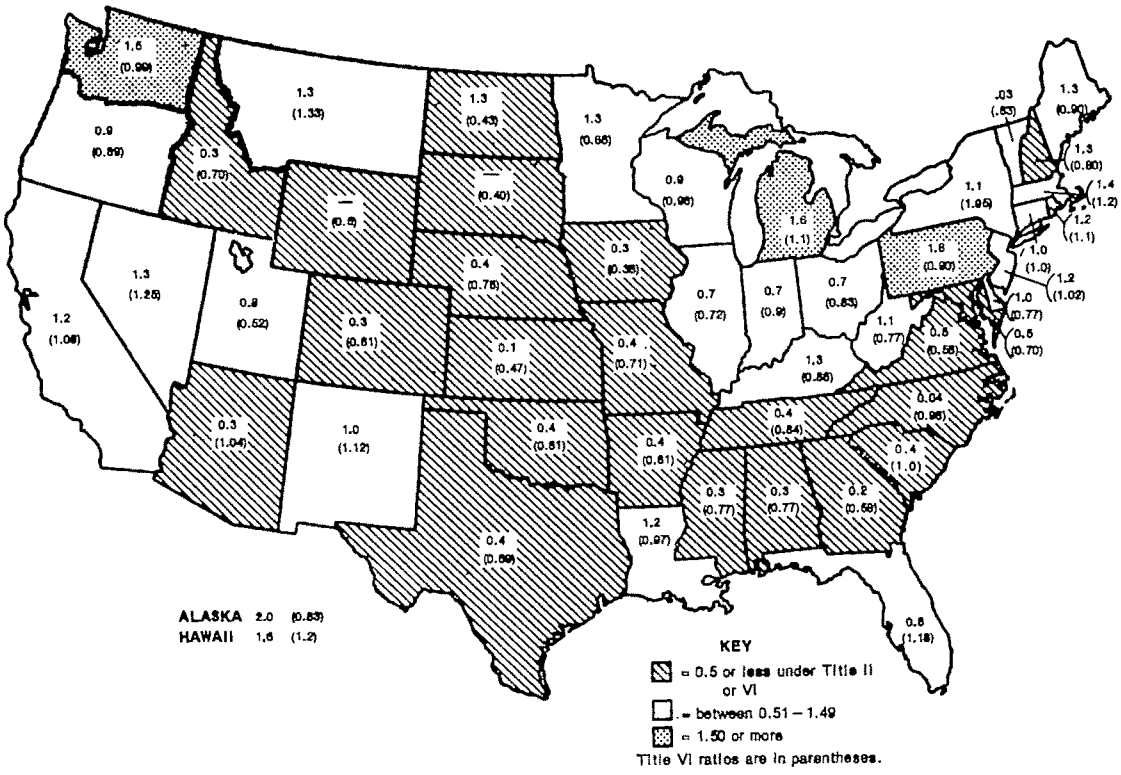

Figure 1. State unemployment—fund share ratios, CETA titles II and VI

ing of rural need for countercylical job creation funds does not coincide with the periods of peak PSE operation; and (*c*) rural areas do not apply for funds for which they are eligible. In addition to structural rural-urban differences that limit allocations to rural areas, certain administrative regulations may discourage rural participation in PSE programs. Finally, rural areas may be unable to utilize and absorb temporarily subsidized workers, making rural public service employment less effective for both participants and communities.

PSE allocations are made on the basis of local unemployment estimates, which are derived largely from local claims for unemployment insurance. As with the generation of any sample statistic, accuracy decreases as the sample size decreases. Rural area samples are smaller than urban samples because of smaller labor forces and because rural areas contain a higher proportion of industries (and jobs) not covered by unemployment insurance. Thus, the generation of local unemployment estimates largely from local unemployment insurance claims increases the margin of error associated with rural unemployment estimates (Wetzel and Ziegler, U.S. Dep. Labor 1960).

Since it is often assumed that the costs of unemployment increase nonlinearly (Comptroller General of the U.S.), PSE programs reserve a portion of available funds for areas of severe unemployment, usually defined as a rate of 6% or 6.5% for three consecutive months. To sustain this level of unemployment requires a labor force in which the unemployed continue searching for work rather than exiting from the labor force. Given the differing recession employment prospects in rural and urban areas, the rural unemployed probably lose their unemployed status more quickly than the urban unemployed. In rural areas, the unemployed can exhaust job search possibilities more rapidly, since rural areas contain fewer potential employers.[6] The rural unemployed are also afforded more opportunities to revert to self-employment or obtain part-time work in, e.g., agriculture.[7] Finally,

[6] Fewer potential employers may also retard labor force entry or reentry until an upsurge in employment is evident, i.e., relatively fewer employers in rural areas lower the cost of information about potential employment opportunities, thus dampening rural unemployment estimates while few jobs exist.

[7] More rural counties tend to have a higher proportion of their labor forces engaged in self-employment. Among the four most sparsely settled county classes, at least 25% of all families re-

rural persons experiencing unemployment have fewer incentives to remain in the labor force in order to search for work and retain eligibility to receive unemployment benefits, since a smaller proportion of the rural labor force is eligible for such benefits. Although rural need exists, it tends to be underestimated with present allocating statistics.

Another factor limiting PSE allocations concerns the temporary nature of public service employment programs and the timing of rural needs. Being countercyclical, PSE programs distribute funds for a limited period of time, biasing the funds distribution to favor areas experiencing severe unemployment. Since changes in the national unemployment rate govern the implementation and duration of PSE programs, the extent of local participation in the national program depends on the elasticity of local unemployment rates with respect to changes in national rates. If rural unemployment leads or lags changes in national unemployment or rural areas have high but stable rather than rapid changes in unemployment, they receive proportionately fewer PSE funds under the current program design.

Several economic factors combine to make the timing of peak rural unemployment vary from peak urban employment periods. Consumption theory predicts that, in a recession, consumers initially postpone their purchases of durable goods (First National City Bank). If durable goods manufacturing is concentrated in urban areas, then urban unemployment should begin rising soon after the onset of a recession. Unpublished USDA data show that in 1972 metropolitan durables manufacturing employment was 62% of total metropolitan manufacturing employment, while nonmetropolitan manufacturing employment was half durables, half nondurables, lending evidence to the hypothesis that urban areas are able to capitalize on their early unemployment rise when seeking limited PSE funds.

Buttressing the tendency of national PSE program operations to be geared to urban needs is the interaction of recent patterns of industrialization and profit-maximizing production decisions. If multiplant employers have been expanding most recently in nonmetropolitan areas, the newer, more efficient capital stocks of these plants should argue for their continued operation with declining product demand. Facing decreasing demand, the multiplant operator can either apportion production among plants or operate only the most efficient plants. Since 63.6% of the new manufacturing jobs created between 1960 and 1970 were in nonmetropolitan counties (Hines, Brown, and Zimmer, p. 36), the most recent vintage of the capital stock in these plants would argue for their relatively later shutdown and layoff periods.

The most serious impediment facing rural areas attempting to secure PSE funds is ineligibility and/or only limited eligibility. However, the administration of PSE programs accentuates rather than mitigates rural difficulties in securing funds. After area certification for PSE funds, local areas must submit approved plans for the expenditure of at least $25,000 (about 2.5 job slots) before funds are actually released. Included in the plan must be the goal of placing at least 50% of temporary PSE hires on the permanent public payroll at the program's conclusion.[8] Nonmetropolitan areas, traditionally providing a lower level of public services, are faced with a relatively higher transition burden even if the percentage transition goal is invariant. The two-stage application process, where rural areas initially apply for funds through their state governments, has produced an array of intrastate allocation formulae. Finally, the local contribution requirement and/or limits on funds used for capital outlays may force additional local outlays unless idle capital stock exists, since even labor-intensive public employment requires some capital.

Public service employment is designed to supplement and expand an area's current range of public services. Areas that are expanding public services have higher probabilities of retaining PSE hires and providing PSE participants with "meaningful" employment experiences, given an intention (in the absence of the PSE) to expand employment in certain directions anyway. If rural areas provide both lower levels of public services and a slower rate of increase in expanding public employment, rural participants are afforded a PSE experience less likely to gain

ported income from some form of self-employment in 1969, while only 10.5% of the core urban families had such income (Hines, Brown, and Zimmer, p. 97). Since unemployment rates among the self-employed are very low, the presence of more self-employed persons lowers the unemployment rate. If a 10% unemployment rate characterizes wage-and-salary workers in both rural and urban areas, and the urban labor force consists of ninety wage-and-salary workers for each ten self-employed persons, while the rural labor force contains a 75-25 division, then the urban unemployment rate of 9% exceeds the rural rate of 7.5% only because rural areas contain more self-employed persons.

[8] This transition requirement is made a goal only under title VI.

them permanent public employment. Until detailed participant data are available, one can only note that county governments (a dominant temporary public employer in nonmetropolitan areas) place the highest percentage of PSE hires in public works, the sector experiencing the lowest post-PSE retention rate.

Another factor that could make rural PSE's less effective than their urban counterparts is the composition of the unemployed in metropolitan and nonmetropolitan areas. Typically, the government labor force has skill characteristics that differ from those of the unemployed. In 1970, 42% of the unemployed had less than twelve years of education, while only 18% of government workers were not high school graduates (Fechter). Thus, even a temporary expansion of public employment produces a tendency to selectively choose participants from the unemployed labor pool. If rural areas contain more of the disadvantaged unemployed, the limitations on expenditures for training and capital outlays tend to direct poorer local areas toward simple tasks that are easy to begin and terminate. Just as the transition requirement can direct participants to particular program areas, the composition of the unemployed can make local decision makers aware of the trade-offs between the numbers and types of jobs created. Assuming unemployed labor pools with similar skill characteristics, local governments wishing to expand health or educational services require more highly skilled participants or more participant training than local governments augmenting construction, repair, or beautification efforts.

The transfer of the locus of control to smaller governmental entities, a prime impetus behind the CETA, assumes that local governments are better able to discern local needs. The CETA invests local prime sponsors with a great deal of influence over any PSE program in their jurisdiction. By deciding which job slots are created, local decision makers also determine the types of participants likely to be hired to fill the job slots created, the wage range and the amount of adjunct training offered, and the probability of retaining the PSE participant with the program's expiration. In rural counties, such local control tends to favor investment in physical infrastructure both because social welfare investments lack a constituency and because risk-adverting local decision makers tend to expand public services in directions already meeting public approval (Zimmerman). Thus, rural counties are likely to offer fewer permanent jobs and less adjunct training with their PSE programs.

Conclusions

This research has assessed geographic equity in the distribution of funds for one series of federal human resource programs, those that expend monies to create temporary public service jobs. Because the allocation formulae used to disburse funds could not capture important differences between rural and urban labor markets, rural need for funds is underestimated. Because rural areas could not enjoy "economies of scale" in applying for federal funds, administrative requirements may have discouraged rural participation. Whether the result of voluntary or involuntary decision, rural America did not receive the share of PSE funds expected, given its share of unemployment.

Most federal programs that affect the nation's stock of human resources have been reactive; they attempt to redress an identified disparity between national norms and group and/or area characteristics. Since these problems are generally identified first in urban areas, programs have been tailored to respond to urban needs. Because human resource programs are too small to meet the universe of need, equity dictates the use of uniform criteria for allocating limited funds, but such allocation formulae could be cognizant of structural differences between groups and/or areas.

To achieve distributional equity in the distribution of public service employment funds, the county (rather than the state) could be made the basic administrative unit. Allocations could be made on a per unemployed person or per capita basis, with per person supplements to counties experiencing severe unemployment or containing concentrations of, e.g., minority persons, poor households, or some other target group. Under such a program, a county's allocation would represent the sum of a per person allocation, derived by dividing the bulk of the total allocation by the national target population, plus per person supplements that reflect concentrations of particular target populations. Such an allocation mode could concentrate funds in local areas while redressing some of the more egregious interarea biases existent under current public service employment programs.

Merely changing the locus of manpower control would not, ipso facto, guarantee that areas of equal need receive equal shares of federal manpower funds. The lack of detailed intercensus data at the county level would force reliance on census benchmarks and subsequent estimates or new data-gathering efforts. Collection of such county level data would increase the cost of administering any PSE program, but the county level data would also be available to direct funding needs for other programs. The current ambiguity surrounding "correct" allocation formulae has shifted the dispute into the legal arena (Raskin). While no simple change can produce an equitable allocation formula, more decentralization could ensure that more remote areas received some minimum level of manpower funds.

Daily Fluctuations in Campground Use: An Econometric Analysis

Ronald A. Oliveira and Gordon C. Rausser

Many recreation activities are characterized by fluctuating use levels over time. This paper presents a theoretical and quantitative analysis of fluctuations in campground use series. Theoretical use functions are specified as the reduced form of a demand and supply system, where the derived demand for campground use is based upon the household production approach to consumer demand theory. A pooled time-series cross-section econometric use model is specified, and its estimated parameters are presented. In addition, campground use series are modeled incorporating Box-Jenkins time-series analysis techniques. Econometric predictions are more accurate relative to autoregressive-integrated-moving-average (ARIMA) predictions.

Key words: campground use, econometric recreation model, recreation demand theory, time-series analysis.

Clawson and Knetsch have noted the problems associated with the variations in time patterns of outdoor recreation use. They also suggested that the time aspects of outdoor recreation use and more explicitly the "extreme time-peaking of demand" have not received sufficient attention in the literature. Barker has suggested expressing recreation carrying capacity in time-associated units. Stottlemeyer has also noted the fluctuations in use levels over the season or year and has suggested time scheduling of visitor use among national park developments so that developments would be used at optimal density and maintenance costs could be optimized. Moreover, the recent discussion by Archer and Shea on tourists' length of stay illustrates the usefulness of daily use models in forecasting daily tourist expenditures, waste treatment needs, water needs etc.

Campground use levels, which are the focus of this paper, may fluctuate considerably from day to day, even though the number of campsites occupied may remain more or less constant. Such fluctuations necessitate corresponding fluctuations in maintenance and regulatory personnel in order to avoid over- and understaffing problems. For instance, managers could easily adjust personnel levels with use level forecast horizons of a month or more in length. Although they may not be able to change personnel levels in the immediate short run, managers could alter the work locations, i.e., concentrate work efforts in certain campgrounds while temporarily ignoring others.

Although the problem of time-varying consumption levels is not limited to outdoor recreation, it has received little attention in the recreation literature. Recreation researchers have traditionally concentrated on explaining the use of a certain recreation activity over a cross section of such activities or the use of a particular type of site over a cross section of such sites (Boyet and Tolley; Clawson and Knetsch; Cicchetti, Seneca, and Davidson). Those studies that have considered recreation use over time have centered on predicting annual participation rates or levels (Clawson, Kalter and Gosse).

In light of the above comments, the purpose of this study is to construct alternative models with which to forecast daily campground use levels over a given season. Two empirical models are presented. The first, an econometric representation, is based upon a conceptual

Ronald A. Oliveira is an assistant professor of agricultural and resource economics, Oregon State University, and Gordon C. Rausser is a visiting professor of business administration, Harvard University.

reduced form use model. It is assumed that the demand for campground use is part of a stepwise utility maximization process and that the present analysis is only concerned with the choice between campgrounds and between camping dates. More explicitly, the decision to camp and the decision on the length of stay are assumed to have been made by the users in the previous stage(s) of their decision process. The second empirical use model, an autoregressive-integrated-moving-average (ARIMA) representation, is fitted using the time-series analysis technique of Box and Jenkins and is employed as a sophisticated "naive" forecasting model, the results of which can be compared with those of the relatively more difficult to estimate econometric model. Although it is expected that the most fruitful application of the two empirical use models would be as input to a national forest recreation simulation analysis, the short-run forecasting abilities of the models are investigated.

Theoretical Formulation

The demand for campground use is assumed to be directly affected by the characteristics of the campgrounds and by the time and expenditures consumers allocate to campground use (i.e., camping). The theoretical foundations for these assumptions are based upon the household production function (HPF) approach to consumer demand theory (Michael and Becker, Ghez and Becker) and the characteristics approach to demand theory (Lancaster), where the latter is viewed as a special case of the former. Following the HPF approach, it is assumed that each camper or user obtains or "produces" basic consumption goods or characteristics from the act of camping at a certain campground, that, in turn, the characteristics are the direct arguments of the user's utility function, and that the user follows a sequential utility maximization process, where the utility function conforms to weak separability, to arrive at the optimal allocation of time and money to camping. Thus, the user derives his "full income" allocation or constraint to camping (Becker, Michael and Becker).

In the nth or camping stage of the consumer's utility maximization process, the user maximizes the portion of his overall utility function that is concerned with campground characteristics, subject to his full income camping allocation and the campground production relationships.[1] These latter relationships may be interpreted either as the user's ability to obtain or produce the desired characteristics from a campground or as the amount of various characteristics available from a campground. The user's derived demand for use of campground j on day t, say, x_{jt}, may be viewed as follows:

$$(1) \quad x_{jt} = f_d(Z_{jt}, s_c) \text{ for } j = 1, 2, \ldots, G \text{ and } t = 1, 2, \ldots, T,$$

where Z_{jt} is a vector of relative levels of basic campground characteristics associated with campground j on day t, s_c is the amount of full income allocated by the user to camping, G is the total number of campgrounds in the set from which the user will select, and T is the length of the relevant camping season.[2] Since it is assumed that the decision to camp and the decision on the length of stay have been made in the previous stage(s) of the user's utility maximization process, other recreation activities and their prices do not directly appear in equation (1) as arguments. Such factors enter into decisions made in previous stages and influence the level of s_c. Given that equation (1) is a derived demand function, the relative attribute or characteristic levels may be viewed as relative prices in the household production function context.

Aggregate demand for using campground j on day t (in terms of number of people) is the sum of all the individual household demands as specified in equation (1). Thus, the arguments of the aggregate derived demand function are the vector of campground characteristics (Z_{jt}) and the full income allocation to camping for all households, say, S_c. Such a specification of campground demand could be employed directly in the analysis of use if the supply of each recreational area is fixed and if supply is always greater than demand. In reality, only the stock of supply is approximately fixed in the short run. By stock of supply is

[1] Actually, the number of previous stages is not important to the present analysis, since this study is only concerned with what happens after the decision to camp has been made. The sequential utility optimization process in another recreation context is further discussed by Rausser and Oliveira.

[2] One might argue that the timing of the camping trip, i.e., the day selection, and the choice of a campground are results of separate decision stages. Such a distinction would need to be determined via personal consumer surveys. Furthermore, given that the objective of the present analysis is to examine variations in use between campgrounds over a given season, it is necesssary to treat the two items jointly.

meant the physical area itself (unit of land) and non–time-varying characteristics (e.g., number of sites). On the other hand, supply may also be interpreted as having a changing quality. In the context of campground use, the flow of supply may be interpreted as the changing quality and availability of supply (e.g., weather). Stock supply characteristics such as the number of campsites may be viewed as flow variables, i.e., changing over time, in a long-term analysis. In the present analysis, use is examined over a given season, and it seems unlikely that physical conditions such as existing facilities will be varied in the short run. Hence, the supply relationship for campground j may be expressed as a function of a vector of characteristics, some constant over the season and some time varying, associated with campground j. One possible interpretation of such a supply function is the number of users possible at area j, i.e., capacity, under varying quality conditions. The explicit definition of such quality conditions or criteria (Seneca and Cicchetti) would obviously be quite difficult to define explicitly and are beyond the scope of this paper. It seems reasonable to argue heuristically that the possible use level for a given "quality index" can vary as characteristics at the campground vary. In turn, the index of quality may vary with use if other conditions remain constant. Although management restrictions as to the number of people per campsite may set an upper limit, exogenous conditions such as weather may keep the total use of the campground below this level.[3]

Combining the above specifications, one obtains a simultaneous demand and supply system, the reduced form of which is campground use (Cicchetti et al.). More explicitly, the reduced form may be stated as

$$(2)\quad X_{jt} = x(Z_{jt}, Z_j, S_c) \text{ for } j = 1, \ldots, G \text{ and } t = 1, \ldots, T,$$

where X_{jt} is defined as the actual use (number of people) at campground j on day t, Z_{jt} is a vector of time-varying characteristics associated with campground j, Z_j is a vector of non–time-varying characteristics, and S_c represents the full income allocation to camping for all households.

As in most empirical applications, the theoretical specification in equation (2) needs to be altered somewhat to correspond to available data. The full income allocation variable S_c cannot be measured empirically. Theoretically, full income is a composite measure of the user's or household's value of time and income allocated to camping. The actual total use at all G campgrounds on day t, or X_{Tt}, is employed as a proxy variable for S_c.[4] Admittedly, these two variables are not equivalent; however, it is reasonable to assume a direct positive correlation between them. The use of any other time-varying reasonable proxy would necessitate the use of camper surveys in order to determine the amount of time and income devoted to this activity.[5] Furthermore, non–site-related exogenous variables such as real income allocations are not particularly desirable in this context, since an attempt is made to account for the choice of a campground across a set of campgrounds.

Two other factors that may be assumed to influence use but are not explicitly listed in equation (2) are past use at campground j and institutional calendar events. For example, past use may be treated as a time-varying characteristic of the campground that influences the household's expectations of congestion at the campground. This interpretation of past use is the result of only one possible structural formulation; it also could result from a partial adjustment formulation, among others.

A priori, one would expect institutional calendar events such as holidays and weekends to have positive influence on use. On the other hand, the influence may be negative if people expect crowded conditions on holidays and stay at home. Holidays and weekends may also influence use via the household "production" process, i.e., many individuals may only be able to engage in the camping "production relationship" on such days. One could therefore assume that their productive capability in this case is limited to nonwork days.

In light of the above discussion, the use function to be addressed empirically in the subsequent analysis may be written as

[3] Clearly, there is a definite need for further theoretical analysis in this area. Nevertheless, the main point is that supply is not fixed in the short run but is a function of the characteristics (some variable) of the campground.

[4] Given that an exogenous factor varies and is unobservable, it follows from the viewpoint of bias that it is better to use a proxy rather than omit this exogenous variable (Wickens).

[5] The variable X_{Tt} could appear in a use function that is motivated by a different structural specification. For instance, it would appear directly if equation (2) was based on an allocative mechanism that allocates a given sum of use over all the possible campgrounds. Estimation and forecasting problems associated with the use of X_{Tt} are noted below.

(3) $X_{jt} = x(Z_j, Z_j, X_{j,t-k}, X_{Tt}, D_t, U_{jt})$
for $j = 1, \ldots, G$ and $t = 1, \ldots, T$,

where D_t is a vector representing institutional calendar events and U_{jt} is a stochastic error term.

Econometric Use Model

Given the above use function and the availability of cross-section data over time, equation (3) may be expressed as a pooled cross-section and time-series (CTS) model. In this context, equation (3) is interpreted as a single equation linear model with $N = G \times T$ observations. With regard to the data base for the constructed model, the campground use series, i.e., X_{jt} in equation (3), was obtained from campground registration forms for twenty-one U.S. Forest Service campgrounds in California for 1970. The observations employed in the analysis were from 1 May to 31 October 1970, resulting in 184 daily use observations. Although the original use series was in daily observations, the econometric model was estimated employing only Saturday observations, since the original series revealed Saturday as generally the heaviest use day of the week. In addition, it was thought that forecasts of Saturday use would be sufficient for most management purposes. Furthermore, the daily observations are most likely characterized by such random fluctuations that it would be difficult to obtain stable econometric predictions for this data base.

Characteristic Variables

The twenty-five characteristics selected for the empirical analysis are listed in table 1. Clearly, some of the characteristics may be measuring the same attribute as another characteristic. Since it was not obvious which characteristics should be omitted, and it was desirable to maintain as much information as possible, it was decided to use the theory of principal components to find a smaller number of variables that would capture most of the variability of the recorded characteristics set. The resulting principal components of the characteristics variables are essentially employed as proxy or instrument variables (Dhrymes, Morrison).

The decision on the number of principal components to use was based upon the percentage of the total variability in the original characteristics "explained" by each principal component. The proportion of the total "vari-

Table 1. Campground Characteristics

Variable	Estimated Regression Coefficients[a]
1. Number of camp units	−4.27
2. Flush toilets available[b]	12.67
3. Vault toilets available[b]	−5.36
4. Combination of flush and vault toilets[b]	15.46
5. Boat launching available[b]	−3.48
6. Boating available[b]	−3.95
7. Swimming allowed[b]	−2.63
8. Fishing facilities[b]	2.51
9. Lake adjacent[b]	−7.11
10. Stream adjacent[b]	9.77
11. Elevation (feet)	−3.13
12. Number of campgrounds within radius of 5 miles	5.33
13. Number of camp units at above campgrounds	1.37
14. Precipitation in June 1970 (1/100 inch)	2.55
15. Precipitation in July 1970 (1/100 inch)	8.85
16. Precipitation in Aug. 1970 (1/100 inch)	0.13
17. Precipitation in Sept. 1970 (1/100 inch)	2.87
18. Precipitation in Oct. 1970 (1/100 inch)	9.85
19. Average annual precipitation, 1965–70 (1/100 inch)	8.14
20. Total precipitation, 1970 (1/100 inch)	9.14
21. Total snowfall, 1970 (1/10 inch)	2.94
22. Average annual snowfall, 1965–70 (1/10 inch)	5.87
23. Number of lakes within radius of 5 miles	7.05
24. Minimum travel time to nearest wilderness area (minutes)	−4.71
25. Population accessibility	−4.87

[a] Estimated coefficients for standardized deviates of campground characteristics using time-series cross-section model in equation (4).
[b] Dummy variable, which equals one if the facility is available at the campground, equals zero otherwise.

ance" in the scatter of the twenty-five campground characteristics attributable to the first seven principal components was 0.87. These components were the only ones that had corresponding eigenvalues greater than one in magnitude. The eighth component accounted for less than 4% of the total variation in the characteristics. Thus, it was thought that the first seven principal components accounted sufficiently for the total variation and that the gain from adding another principal component would not be worth the loss in degrees of freedom.[6]

There is not general agreement as to the interpretability of principal components in an economic context. Dhrymes states that principal components, especially when derived from a correlation matrix, cannot generally be interpreted in a meaningful way. Morrison, however, suggests that the elements of the eigenvectors, i.e., their magnitude and sign, may be interpreted as indicating the importance of the corresponding variable (or campground characteristic in this case) in contributing to that specific component. If one only considers those eigenvector values of a relatively large value, the dimensions of the various principal components can be defined in terms of the variables corresponding to these large eigenvector values (Hendee et al.). By considering only those eigenvector values with absolute values greater than or equal to 0.25, the dimensions of the seven respective campground characteristics principal components are interpreted as follows: (*a*) higher than average precipitation at a relatively low elevation with swimming and fishing available; (*b*) lake with boating and alternative campgrounds available or nearby; (*c*) fishing stream and nearby lakes; (*d*) stream and nearby lakes but with relatively smaller number of camp units and close to a wilderness area; (*e*) low snow fall, stream, and remote; (*f*) primitive toilet facilities without nearby campgrounds and lakes but with boating; (*g*) without combination flush and vault toilets but not close to a wilderness and with September precipitation.

Temperature Variables

In the conceptual discussion of use functions, weather conditions are given as an example of a campground time-varying characteristic. Time-varying characteristics are viewed as components of the flow of supply that influence the accessibility of a campground. Similarly, when treated as a time-varying characteristic, weather conditions will have a bearing on the overall attractiveness of a campground and influence its demand.

Since little precipitation occurred during the observation period employed (i.e., 1 May–31 October 1970), it was decided to measure main weather conditions by temperature readings. Daily maximum and minimum temperature readings were recorded for the weather reporting station nearest each campground and for a central city in each California county during the observation period. To make the analysis manageable, temperature readings for the three counties from which the most users came to each campground were employed.[7]

Use is not assumed to be directly influenced by the actual county temperatures but rather by the relative difference between the "at-home" temperature, i.e., the county temperature, and the temperature at the campground. Specifically, it is hypothesized that if the "home" (county) temperature is relatively hot, say, 100°, and if the campground vicinity is experiencing mild or cooler temperatures, say, 75°, then there will be a strong positive temperature attraction influence on the people in the country. Given this hypothesis, a temperature attraction variable was constructed. This variable ranged in magnitude from 10 to 0, where 10 is the maximum amount of attraction. Using only the three heaviest use counties associated with each campground, each possible county-area temperature combination (within 5° intervals) was assigned a value ranging from 10 to 0, based upon the temperature attraction hypothesis. The assigned value was related to the difference between the campground and the county temperatures and the actual county and campground temperatures. In other words, a difference of 10° would receive different values depending upon the actual county temperatures. It was assumed that, if the county's temperature was low, a warmer area would be attractive up to a point, i.e., until the campground became too warm.[8]

[6] The eigenvalues and their corresponding eigenvectors for the first seven principal components along with their contribution to the total "variance" are available from the authors upon request.

[7] Admittedly, by excluding the other fifty-five California counties, one is ignoring information; however, it was thought that this omitted information was minimal, since in most cases only a few counties contributed to the majority of use at each area. In fact, the actual empirical analysis indicates that only the heaviest origin use county has a significant influence on use.

[8] The values assigned for the maximum and minimum temperature combinations are available from the authors upon request. As expected, the values selected are somewhat arbitrary and

Empirical Econometric Results

Alternative forms of time-series exogenous variables were considered and analyzed in the context of equation (3).[9] Not surprisingly, many of the temperature variables were eliminated due to extremely high intercorrelations, i.e., the temperature attraction variables associated with the three heaviest use counties for each area were often highly correlated due to similarities in temperatures as well as similarities in travel times (which were used to form interaction variables). The following variables were selected as predetermined variables for the final model, where t represents Saturday or weekly observations: total use at all campgrounds on Saturday t (X_{Tt});[10] use lagged one observation (X_{jt-1}); use lagged two observations (X_{jt-2}); temperature attraction variable (minimum temperatures) associated with heaviest use county (Z_{j1t}); minimum temperature at campground j on Saturday t (Z_{j2t}); interaction term formed by dividing Z_{j2t-1} by the travel time in minutes from the heaviest use county to campground j (Z_{j3t}); first characteristic principal component (based upon standardized deviates of the characteristic variables) of campground j (Z^*_{j1}); second through seventh characteristic principal components of campground j ($Z^*_{j2}, \ldots, Z^*_{j7}$).

The pooling of the cross-section observations for the eighteen campgrounds and the twenty-five Saturday observations resulted in far more pooled observations than needed for estimation purposes.[11] Since it is also desirable to have separate data with which to test an econometric model, especially one to be used for forecasting, some of the campground data were saved for testing the forecasting performance of the estimated model. Thus, the eighteen campgrounds were divided into two arbitrary groups, A and B. The econometric estimation results for the pooled data from group A are given below. In a subsequent section, the results of using the estimated model to forecast the use levels for group B based upon the actual data for that group are presented. The estimated model based upon group A data is as follows:

$$
\begin{aligned}
(4)\quad X_{jt} = {} & -37.3 + 0.0084\,X_{Tt} + 0.77\,X_{jt-1} \\
& (-1.0)\ (2.9)\qquad (11.0) \\
& -0.12\,X_{jt-2} + 10.1\,Z_{j1t} - 1.8\,Z_{j2t} \\
& (-1.9)\qquad (2.1)\qquad (1.9) \\
& + 399.5\,Z_{j3t} + 15.4\,Z^*_{j1} - 7.9\,Z^*_{j2} \\
& (3.1)\qquad (3.8)\qquad (-1.9) \\
& -0.23\,Z^*_{j3} + 9.6\,Z^*_{j4} + 6.0\,Z^*_{j5} \\
& (-0.02)\qquad (0.7)\qquad (0.7) \\
& - 18.4\,Z^*_{j6} - 19.2\,Z^*_{j7} \text{ for } j = 1, \ldots, G \\
& (-2.1)\qquad (-2.0) \\
& \text{and } t = 1, \ldots, T,
\end{aligned}
$$

where the numbers in parentheses are the approximate t-statistics for the corresponding coefficient estimates and $R^2 = 0.77$. The time-series predetermined variables had estimated coefficients that were of the expected sign and that were significantly different from zero.[12] One might question the fruitfulness of including the temperature attraction variable (Z_{j1t}), the campground minimum temperature (Z_{j2t}), and the temperature interaction variable (Z_{j3t}) all in the same equation. As one would expect, these variables are highly correlated; however, they all have significant coefficient estimates, indicating they may account for different influences on use and should be useful for forecasting purposes. The temperature attraction variable is assumed to account for the "drawing power" of temperature differences between the campground and its heaviest use county. On the other hand, the significant negative coefficient estimate for the campground's minimum temperature suggests that the actual minimum temperature has a negative relationship to use. Moreover, this suggests that there are temperature effects not fully accounted for in the attraction variable. There seems to be a contradiction between the estimated coefficients for Z_{j2t} and Z_{j3t}. A priori, one would expect the coefficients for

influenced by subjective opinions. What is important, however, is that the values should be selected in a consistent manner. If so, based upon the hypothesis given above, one would expect to find a positive relationship between use and the temperature attraction variables.

[9] The residual terms in equation (3) are assumed to follow a first-order auto-regressive scheme and are specified as cross-sectionally heteroscedastic and mutually uncorrelated. To account for these problems and for the relationship between the lagged dependent variables and the error terms, a five-stage procedure is employed to obtain consistent estimates of the parameters. The details of this estimation procedure are reported in Rausser and Oliveira.

[10] Powell examines an aggregate variable similar to X_{Tt} as a common regressor in a system of equations and shows that in this context the disturbance covariance matrix is singular. This problem is obviously avoided in the present single equation CTS model.

[11] Of the original twenty-one campground use series, three were omitted due to apparent data inaccuracies.

[12] The use of the word significant is not strictly correct, since the ratio of the estimated coefficient to its associated standard error (under the null hypothesis that the true unknown parameter is zero) is only approximately distributed as a t (Rausser and Oliveira).

these variables to have the same sign; however, the expected linear relationship between travel time and use is negative. Thus, the expected relationship between the reciprocal of travel time and use would be positive. The empirical results suggest that the positive effect of the reciprocal of travel time outweighs the negative influence of the minimum temperature, resulting in a net positive relationship.[13]

The interpretation of the estimated coefficients for the principal component variables is somewhat ambiguous. Nevertheless, those coefficients that are significant suggest that the presence of swimming and fishing facilities are positive influences on use levels. These results also suggest those campgrounds with primitive toilet facilities and those located at longer distances from other campgrounds have lower use levels. This implies that clusters of campgrounds are more popular and that campers prefer flush toilets to vault.

Another procedure for examining the regression results pertaining to the campground characteristics is to transform the estimated coefficients of the principal component variables to coefficients for the standardized deviates of the original characteristic variables. These estimated coefficients are presented in table 1. Again, the relatively larger coefficients suggest the importance of flush toilet facilities and a stream. The coefficients for characteristics 1, 12, and 25 imply that clusters of larger campgrounds close to population centers are characterized by higher use levels. It also appears that an adjacent lake is not a positive attraction but that nearby lakes are. The empirical results imply that *ceteris paribus* campgrounds immediately adjacent to a lake will have relatively lower levels of use than those that are near or within a short distance to lakes. The large positive values for the precipitation characteristics are surprising and seem contrary to reasoning,

Lime found that fishing and waterfront campsites were important variables in the selection of campgrounds. The results presented above, although somewhat ambiguous, support his findings. Shafer and Thompson also noted the high positive correlation between use levels and water-recreation variables and campground size.

[13] In addition, the sign of this interaction term may be influenced by the lag factor. The direction of such an influence is unclear. The above expectations with respect to signs of coefficients are only correct if all variables are orthogonal—they obviously are not.

Box-Jenkins Campground Use Model

In the previous section, an econometric representation of the campground use model specified in equation (3) was presented. This section presents an alternative model of the campground use series that does not directly include exogenous variables and that is estimated with daily rather than weekly observations. The use series is modeled on the basis of its present and past observations in terms of an autoregressive-moving-average (ARMA) model as developed by Box and Jenkins.[14]

Incorporating the notation of Box and Jenkins, the general multiplicative seasonal autoregressive-integrated-moving-average (ARIMA) model for a seasonal series X_t, $t = 1, 2, \ldots, T$, with a known period s can be written as

$$(5)\quad \phi_p(B)\Phi_P(B^s)(1-B)^d(1-B^s)^D X_t = \theta_q(B)\Theta_Q(B^s)a_t,$$

where a_t is a random disturbance assumed to be distributed as $N(0, \sigma^2)$; B is a backward shift operator such that $BZ_t = Z_{t-1}$ and $B^kZ_t = Z_{t-k}$; $\phi_p(B)$ is the regular autoregressive operator of order p, i.e., $\phi_p(B) = (1 - \phi_1B - \phi_2B^2 - \ldots - \phi_pB^p)$; $\Phi_P(B^s)$ is the seasonal autoregressive operator of order P; d is the number of regular differences; D is the number of seasonal differences; $\theta_q(B)$ is the regular moving average operator of order q, i.e., $\theta_q(B) = (1 - \theta_1B - \theta_2B^2 - \ldots - \theta_qB^q)$; $\Theta_Q(B^s)$ is the seasonal moving average operator of order Q; and s is the order of the seasonal difference. Equation (5) is an ARIMA model of order (p, d, q) times $(P, D, Q)_s$, explained in some detail by Box and Jenkins.

Using a seasonal difference of order 7, i.e., a weekly season, and daily observations, the nine campgrounds in group A are each fitted to equation (5) following Box and Jenkins' four-stage modeling procedure, i.e., (*a*) specification, (*b*) identification, (*c*) estimation, and (*d*) diagnostic checking. (The estimated autocorrelation and partial autocorrelation functions for the use series and the results of the diagnostic residual tests are available from the authors upon request.) The "best fitting" model for each campground in group A is listed in table 2. Campgrounds 1, 10, 14, and 20 are relatively accessible to large population centers and, consequently, their use series are

[14] One can easily demonstrate that an ARMA model is derivable from a structural econometric model if each exogenous variable is assumed to be generated by an ARMA process (Rausser and Oliveira).

Table 2. Campground ARIMA Models

Campground	Model	Estimates of Parameters

	$= (1 - \theta_1 B - \theta_{11} B^{11})a_t$	$\hat{\phi}_9 = -0.14$	$\hat{\theta}_{11} = 0.23$
18. Oak Grove	$(1 - \phi_1 B)(1 - B)(1 - B^7)X_t$	$\hat{\phi}_1 = 0.31$	$\hat{\theta}_2 = 0.20$
	$= (1 - \theta_2 B^2 - \theta_{16} B^{16})(1 - \Theta_7 B^7)a_t$		$\hat{\theta}_{16} = -0.25$
			$\hat{\Theta}_7 = 0.91$
20. Indian Valley	$(1 - \phi_1 B)(1 - B)(1 - B^7)X_t$	$\hat{\phi}_1 = -0.08$	$\hat{\theta}_4 = 0.15$
	$= (1 - \theta_4 B^4)(1 - \Theta_7 B^7)$		$\hat{\Theta}_7 = 0.79$

characterized by large weekly cycles, i.e., heavy weekend use. Their ARIMA models are all characterized by a relatively large seasonal parameter, and all, except that for campground 10, have a seasonal difference. In contrast, campgrounds 6 and 16 are relatively isolated from major population areas and are most likely characterized by less fluctuating use levels, i.e., campers will tend to stay for more than just a weekend. As expected, their models do not contain seasonal parameters or seasonal differences. Campground 16 is located next to a lake and has boating facilities, which may encourage longer camping stays. Campgrounds 8, 12, and 18 have models with dominant seasonal aspects but are not relatively accessible to large population areas. These three campgrounds may appeal to weekend campers, since campground 8 is quite large (i.e., will not fill up as quickly) and the other two offer more modern facilities such as flush toilets.

Forecasting Campground Use

The econometric and ARIMA models presented in the last two sections are used as forecasting equations in this section. The campgrounds are divided into two groups so as to have a "postsample" set of data with which to test the forecasting models. Given the campground postsample period consisted of observations on different campgrounds, i.e., group B, it was decided to select one model from the ARIMA models listed in table 2. Preliminary estimations for all of the group A campgrounds using all the models in table 2 indicate that the more accurate, in terms of root-mean-square error (RMSE), was the model for campground 6. Hence, this model is employed as a representative campground ARIMA forecasting model.

Independent econometric and ARIMA sample period estimations and postsample period predictions are made for seven-, fourteen-, and twenty-eight-day estimation and forecast spans. These time spans are considered to be adequate for testing the short-run forecasting performances of the models. The econometric model is based upon Saturday observations. Thus, the above forecast spans correspond to one, two, and four period ahead predictions. For the ARIMA estimations and projections, actual seven-, fourteen-, and twenty-eight-day spans are used, since these models are estimated with daily observations. For the econometric estimations and predictions, the exogenous variables are set at their actual levels. These actual values lead to *ex post* forecasts from the econometric model. Such predictions may be viewed as forecasts

that would have been made by a forecaster endowed with perfect foresight with regard to future values of exogenous variables (Nelson, p. 902). In a practical situation, forecasted values of the exogenous variables need to be employed. Forecasts of X_{Tt} at first glance appear to be the most difficult to obtain. Fortunately, forecasts of aggregate annual use are generally made for most recreation areas such as a national forest. One could distribute an estimate of aggregate annual use over the season by using a modified ARIMA model and substitute this proportioned daily estimate in the forecasting equation.

The RMSE's for the sample period estimations and postsample (i.e., group B) predictions using the econometric and ARIMA models independently are given in table 3. The sample period econometric estimations are generally more accurate relative to the ARIMA estimations. The econometric RMSE's are smaller than the seven-day ARIMA RMSE's for six of the nine sample period campgrounds. Since the sample and postsample observations are composed of different campgrounds, accuracy of the models for the two periods cannot be directly compared. For the postsample period the ARIMA predictions are more accurate relative to the econometric predictions for seven of the nine campgrounds. One possible explanation for this reversal of the relative accuracy is the observation base for the econometric model, which is composed of different campgrounds (i.e., cross-section and time-series observations), while the ARIMA model is based upon observations of only one campground. The econometric model may be too aggregative relative to the ARIMA model to be useful in nonconstruction period predictions.

Predictions from both the econometric and ARIMA models are combined by various schemes of composite predictions. For example, by regressing the actual use levels on the two forms of predictions, we obtain estimates of "composite weights" in terms of the regression coefficients. The estimated composite weights are then employed to obtain linear composite predictions. If one assumes the two predictions to be independent, the composite weight estimates can also be used as a measure of the relative importance of each predictor, i.e., econometric or ARIMA, in forming the composite prediction. Given that the econometric predictions employed actual values of exogenous variables, the econometric prediction weight generally is close to one. With each composite procedure tested, it was found that more accurate results in terms of RMSE are obtained with the composite predictions than with the individual predictions alone. (The results of the composite predictions analysis are available upon request. A more detailed discussion of composite prediction in the context of wilderness use is presented in Rausser and Oliveira.)

Conclusion

The main conclusion of the above analysis is that daily campground use levels over a season can be modeled with some success. Two types of empirical models were employed. The first, a pooled cross-section and time-series single equation econometric model, was

Table 3. RMSE for Econometric and ARIMA Predictions

	Campground								
Period and Model	1	6	8	10	12	14	16	18	20
Sample period									
Econometric	83	18	108	67	38	26	61	72	29
ARIMA									
7-day	119	9	115	70	48	28	60	70	34
14-day	152	14	182	111	62	37	104	77	48
28-day	219	18	292	148	84	53	168	119	66
Postsample period									
Econometric	184	128	38	101	48	59	82	144	133
ARIMA									
7-day	116	48	29	74	57	74	60	105	71
14-day	160	76	46	92	78	86	75	188	113
28-day	180	115	76	127	117	120	99	322	153

based upon a causal reduced form use model. The estimated coefficients of the econometric model agreed with the expected causal relationships, and the overall model provided relatively more rigorous support for previous recreation research findings. The ARIMA models, the second empirical approach, provided a time-series model to compare with the more complex and difficult-to-estimate econometric model. Although the ARIMA model provides no information as to the causal factors behind campground use and its fluctuations, the model is relatively easy to employ and could be useful in structuring the lag relationships of an econometric model (Rausser and Oliveira).

The forecasting performance of the two models was also analyzed. Since actual values of the exogenous and lagged endogenous variables were employed to obtain the econometric predictions, it was not surprising that they were more accurate than the ARIMA predictions. It is doubtful, in an application where it would be necessary to use forecasted values of the exogenous variables, that the econometric predictions would be superior to the ARIMA values. The accuracy of forecasts in terms of RMSE can often be improved by combining the two separate predictions. For instance, in this application, the RMSE of the composite predictions were found to be, at a minimum, 5% smaller than the RMSE of the more accurate of the two individual predictions.

One of the more interesting features of the above discussion is the incorporation of the household production function concept into recreation demand analysis. This seems to be an intuitively appealing way to view recreation demand and is quite similar to the "multiple satisfaction approach" to hunting as described by Hendee. A fruitful extension of this paper would be a theoretical development of recreation demand based upon a combination of the HPF approach with the sociological implications of the multiple satisfaction approach. Such an analysis would hopefully investigate the desired attributes or characteristics of a camping experience, i.e., the basic commodities which the user is seeking or "producing" via campground use.

The results generated in this paper can be employed directly or indirectly in more applied contexts. Initially, direct benefits can be obtained by using the use time-series models, especially the ARIMA type, to allocate and disaggregate the annual use level predictions from government agencies (U.S. Dep. Interior). Projections of annual use could be distributed over the season in ARIMA fashion if one assumes various starting levels. Moreover, a causal model such as the econometric model discussed above could be employed to allocate aggregate use projections across recreation subareas and to forecast peaking problems over time as well as space. Such projections could also be made available to the public in order to forestall crowding conditions and turn-aways.

More indirect benefits of the above analysis could be obtained by employing daily use models, such as the ARIMA or econometric model presented above, in large-scale recreation systems models or in dynamic aggregate demand studies. The use equations, or similar ones, could serve as exogenous inputs into a national forest recreation simulation model, where recreation use levels at several different campgrounds and the resulting traffic flows and physical impacts are analyzed over time. Such a simulation analysis could be similar to the wilderness area simulation model developed by Krutilla and Smith. Desirable addition to the present analysis in such an application would be the development of quantitative models for camper arrival rates as well as the length of stay.

Income Distributional Effects of the California Land Conservation Act

David E. Hansen and S. I. Schwartz

The distribution of program benefits of California's use-value assessment program has been a major issue in the political debate concerning the program's desirability. This study examines the income distributional effects of program benefits for a sample of participants in Sacramento County. The fraction of benefits received by lower income landowners was quite large when compared with their share of total income. Benefits received by lower income farmers were sufficient to cause a significant positive shift in farm income distribution, as measured by the Gini coefficient. For nonfarmers, the shift in the income distribution was slight.

Key words: agricultural land preservation, income distribution effects, use-value assessment.

Although most public programs do not contain explicit distributional goals, the incidence of their costs and benefits may become a major political issue. Under such circumstances, politically relevant policy analysis requires that distributional information be provided to decision makers so that informed decisions can be made. The California Land Conservation Act (CLCA) provides an example of a program where the distribution of benefits has become a major political issue even though distributional goals were not explicitly stated in the Act. This paper discusses the emergence of the distributional impacts as an important issue and analyzes the incidence of program benefits among CLCA participants in Sacramento County. The methods and findings should aid policy makers in California as well as other states where similar programs have been enacted or are being considered.

CLCA Background

The primary goals of the CLCA are to preserve prime agricultural land, discourage urban sprawl, and maintain a viable agricultural economy in California.[1] A principal feature of the CLCA is the contractual agreement between landowner and the appropriate local government (usually the county) under which the landowner must retain land in agricultural or related open space use for a minimum of ten years. In return, the land is taxed on the basis of income for agricultural use, rather than on the land's market value. The contract is automatically extended each year unless either party issues a notice of contract nonrenewal. If not renewed, the contract enters a nine-year run-out phase, which requires land to be assessed at an increasing rate that is higher than use value but lower than market value. Of the thirty-five states that at latest count have adopted use-value legislation, California is considered to have one of the two strongest programs because of the stability provided by the long-term contract (Gloudemans).

Political Support and Success of the CLCA

Original political support for the CLCA came largely from the agricultural sector and from

Giannini Foundation Paper No. 391. The authors wish to thank Jeanette Tighe and Linda Thorpe for their assistance in gathering and analyzing the data and Chuck Mundy, Office of the Assessor, Sacramento County, for his exceptional cooperation. The research was supported by a grant from the Rockefeller Foundation to the Division of Environmental Studies, University of California, Davis. The authors share equal responsibility for this paper.

[1] The CLCA is also widely known as the Williamson Act. The legislation establishing the Act can be found in the California *Government Code*, sections 51200–295. More detailed discussions of the important provisions of the CLCA are available in Wagenseil and in Stanford Environmental Law Society. An excellent description of use-value assessment programs throughout the United States is contained in Gloudemans.

conservation interests who endorsed the legislation because of its promise for preserving open space and agricultural land (Snyder). By 1973, it was clear that political support for the program had broadened. At a legislative hearing on the CLCA, testimony in support of the Act was given by the California Farm Bureau Federation, California Cattleman's Association, and California Forest Protection Association, as well as by the California Chamber of Commerce, representatives of the County Supervisors's Association of California, the County Assessor's Open Space Committee, and individual county planning directors (California Legislature 1973). In 1975, a task force on the preferential assessment of property, established by the legislature to recommend changes in the CLCA, recognized the support and acceptable performance of the Act in recommending that "all agricultural lands in commercial use . . . should be eligible for preferential treatment" (Hauck and Odland).

With forty-six out of the state's fifty-eight counties participating as of 1975, the program is generally considered to be successful in terms of overall participation. The total enrolled acreage was over 13.7 million, or approximately 44% of all privately owned agricultural land in the participating counties. Of this total, 4.18 million acres were classified as prime agricultural land, representing 40.7% of the total prime land in the participating counties.[2] Tax reductions from CLCA contracts amounted to $18.4 million in fiscal year 1974–75 and were estimated at $22.1 million for 1975–76 (California Resources Agency, Dep. Conservation).[3] Thus, to the extent that property tax relief contributes to a viable agricultural industry, the Act may be judged to be successful in meeting one of its goals. However, despite the high enrollments and the stability of the long-term contracts, the CLCA has been criticized for its limited influence on land conversion at the urban fringe (Schwartz, Hansen, and Foin; Gustafson and Wallace). Undoubtedly, the mixed success in meeting all of its explicit goals has been a factor in the increased political interest in the distributional impacts of the Act.

A number of writers have emphasized the need for greater attention to be given to distributional impacts—because of the political significance of such information or because of the belief that such information should be part of a comprehensive evaluation (Maass; Bonnen; Bromley, Schmid, and Lord; Kalter and Stevens). In our view, the need for distributional analysis is especially strong for the CLCA program because the distribution of benefits has become an important policy issue in California and is likely to become important in other states that have use-value assessment programs.

Several reasons exist for the emergence of distributional impacts as an important issue. There is widespread belief that the CLCA is intended to aid (or should be directed towards) smaller landowners who, as a group, are perceived to be less able than others to withstand the tax increases at the urban fringe or near rural subdivisions (Fellmeth, Sheedy, Odland). The use of preferential taxation to aid the small farmer has been supported by legislators, public interest advocates, land reform groups, and rural development groups ("How Rich People Farm the Treasury," Rural America). Such public support for the small farmer may also be traced to various federal programs and, in recent years, to the growing reaction to very large corporate-owned agricultural enterprises and the entry of syndicates into agriculture for the purposes of obtaining tax loss benefits.[4]

Undoubtedly, a major impetus for raising the distribution of CLCA benefits to a prominent political position came from a Nader task force study led by Fellmeth. In the strongest criticism of the CLCA to date, the program was faulted for bestowing millions of dollars of benefits upon giant corporate landowners, while providing little benefit to small landowners. The evidence consisted of a list of the largest beneficiaries of the Act, the amount of land each had enrolled, and the total tax reductions received. The list does indeed include giant corporations, some primarily nonagricultural, who accounted for "over one-fifth of all land affected by the Act" (Fellmeth, p. II-37). The attack struck a responsive chord with some members of the

[2] These estimates are based on a state inventory of agricultural lands (California Legislature 1969) and 1975 enrollment figures. The percentage of eligible prime land that is enrolled would be somewhat higher since some prime lands are not eligible because of location or size of parcel. In the total agricultural land estimate, this is probably more than offset by some contracted forest lands not included in the agricultural land totals.

[3] Part of this tax loss to local governments was reimbursed by the state's subvention program, which repaid $10.47 million in 1974–75 and was expected to reach $11.20 million in 1975–76 (California, Resources Agency, Dep. Conservation).

[4] At least one state, Minnesota, has restricted participation to noncorporate owners in its use-value assessment program (Rural America).

state legislature, and preliminary efforts were made to restrict participation in the CLCA program on the basis of size of enrolled acreage, distance of residence from enrolled land, levels of benefits paid, and corporate status of participants (Gonzales, Schwartz et al.). Although legislation restricting enrollment has not resulted, interest remains in such restriction. The impact of the Fellmeth criticism and the continuing importance of the distributional issue was noted recently by Wallace, now director of the State Department of Food and Agriculture, and Gustafson:

> On the basis of data on the concentration of tax reductions in 1970, the California Land Conservation Act of 1965 has been criticized because large corporate-conglomerate landowners have obtained very large tax reductions as a result of the Act (Danielson 1971; Fellmeth 1971). Current data on the distribution of tax reductions are needed. If it cannot be demonstrated that the distribution of tax reductions has become less concentrated since 1970 (which seems unlikely), support for the Act in the future may be limited unless a method can be found to confine these tax reductions to small and moderate-sized agricultural units (p. 383).

Study Area and Objectives

Sacramento County, the area selected for analysis, is a county that has an important agricultural sector as well as a major urban area. The county ranks twenty-third among California's fifty-eight counties in total value of agricultural products sold and eighteenth in harvested cropland area (U.S. Dep. Commerce 1972). Agriculture is diverse, as indicated by the ten leading commodities in 1975: cattle and calves, corn, milo, tomatoes, pears, wheat, rice, irrigated pasture, sugar beets, and alfalfa hay (in decreasing value of production). Harvested or bearing acreage in field, seed, fruit and nut, and vegetable crops totaled 383,755 acres in 1975. Field crops accounted for approximately 92% of this acreage, with vegetables, seeds, and fruit and nuts sharing about equally in the remaining acres. Within the field crop category, rangeland, irrigated pasture, and hay production accounted for 65.7% of the acreage (Sacramento County, California 1975).

The average farm size in Sacramento County (315 acres) is approximately 30% smaller than the statewide average; however, the average number of harvested acres per farm (149.5) exceeds the statewide average by 10%. The average size of Sacramento County farms is 19% below the nationwide average, but harvested acreage per farm is 22% above the national average. Thus, the county appears to be characterized by smaller than average livestock operations and other activities involving nonharvested acreage, but it is somewhat above the state and national average for harvested acreage per farm.[5]

Ownership concentration of harvested cropland provides a further measure for comparing counties. In California, the concentration of harvested acreage in large farms (over 2,000 acres) varies greatly among counties (from 0 to 70%). Sacramento County, with 17.9% of its harvested cropland in large farms, is well below the statewide figure of 35.6% but is above the national average of 14.3%. Of the forty-four counties that participate in the CLCA, Sacramento ranks twenty-eighth in percentage of harvested cropland in large farms. In terms of small farms (under 100 acres), Sacramento County, with 68% of its farms in this category, is below the state average of 77% but above the national average of 65% (U.S. Dep. Commerce 1972, 1973).

Although the great diversity found in California makes it difficult to define a representative county or generalize widely from the results of this analysis, we believe that Sacramento County is sufficiently representative of a substantial number of counties within the state (and elsewhere) to provide important income distributional information to policy makers. By examining the benefits to all CLCA landowners within the county, the present study seeks to overcome the deficiencies of the only previous distributional analysis of use-value assessment, which focused solely on the largest beneficiaries of the CLCA (Fellmeth)—an approach that could not evaluate the extent to which lower income landowners benefitted from the program.

The present analysis examines income distributional impacts of the CLCA over the entire population of participants in Sacramento County in terms of (*a*) proportions of benefits received by participants according to their income level, (*b*) the differential effect of CLCA benefits on income according to income category, and (*c*) differences between farmer and nonfarmer participants.

---

[5] Among CLCA respondents in Sacramento County, the average size of holding of 453 acres is considerably above the county average. This is to be expected, since many smaller sized holdings are in transition to urban uses.

Methodology and Methodological Problems

Information used in this study was obtained from a mail survey of all CLCA contract holders in Sacramento County in 1973. Respondents were asked to indicate the appropriate category of net taxable family income and their tax filing status (e.g., single, married filing joint return, etc.). From this information the state and federal income tax rates were determined for each respondent. An overall response rate of more than 65% was achieved, with 50.3% usable questionnaires containing information on income. Due to a concern that the sensitive questions relating to income might cause the sample to be unrepresentative, nonrespondents were compared with respondents according to number of parcels owned, acreage owned, and benefits received from the Act. No biases that would indicate lack of representativeness of the sample were detected by any of these measures.

For each parcel under CLCA contract, the market and CLCA assessed values and total property tax rate were obtained from the Sacramento County Assessor's Office.[6] Applying the property tax rate to the difference between market and CLCA assessed values for each contracted parcel, the gross CLCA benefit was obtained. The gross benefit was multiplied by the appropriate income tax rate and the result was deducted from the gross CLCA benefit to obtain the net CLCA benefit. "Preprogram" taxable income was estimated for each respondent by subtracting the gross CLCA benefits from the indicated net taxable family income. Gini coefficients were then computed for the pre- and postprogram distribution.[7]

The treatment of the two distinct types of corporations found in California agriculture poses several problems. In the first type of corporation, ownership is similar to the typical industrial corporation with large numbers of shareholders. Agricultural endeavors may provide a small fraction of the earnings of these corporations. The other entity is the subchapter S corporation owned by a small number of individuals, typically within a single family. Ideally, a distributional analysis would seek to determine the eventual distribution of benefits to all individual holders of corporation stock—clearly a most difficult task. Bonnen apparently resolved this problem by treating corporations as individuals. For purposes of this analysis, subchapter S corporations are considered as families (the unit of measure used for the noncorporate cases). Benefits received by nonsubchapter S corporations were calculated and compared with the benefits received by all families but were not included in the income distribution calculations because of our inability to estimate total income earned by corporations.[8]

The choice of an appropriate measure for evaluating the distributional effect of a program is not clearcut. Objections can be raised to any of the possible income or wealth measures that have been used by previous researchers. In an extensive discussion, Weisbrod and Hansen proposed a combined income-net worth measure. While appealing, the problems of obtaining such information by survey, especially when added to the need for information from which to estimate tax rates, caused this approach to be discarded. Accordingly, net taxable family income was selected since it allowed accurate determination of the tax rate while providing a reasonable income measurement as a basis for the distributional analysis.

Distribution of CLCA Benefits Among All Respondents

Respondents were categorized into nine different income groups ranging from under $6,000 to over $50,000, and the net CLCA benefits received by each income group were tabulated (table 1). Results show that a large percentage of program benefits accrue to the lower income groups. The two lowest income groups, comprising 22.4% of the total sample, received only 5.0% of the net taxable postprogram income but received 20.9% of the net CLCA benefits. The next two lowest income groups ($8,001–10,000 and $10,001–13,000) received a share of net benefits (24.3%) even greater than their proportion of the population (15.5%), while receiving only 7.5% of the total income. Thus, the four lowest income groups, which received 12.5% of the net taxable income, received 45.2% of net CLCA benefits.

[6] Under California law, land must be appraised at its market value, with the assessed value being, in all instances, 25% of market value.

[7] Calculation of the Gini coefficient of income concentration is described by Miller (pp. 274–76).

[8] Attempts to obtain accurate income information from the corporate respondents were unsuccessful, most wishing not to divulge earnings. Since the corporations were few in number, we believe this treatment does not greatly distort the results.

Table 1. Pre- and Postprogram Income Distribution Among All Respondents, 1973 Survey

	Preprogram			Postprogram			
		Cumulative Percentage of			Cumulative Percentage of		
Income Range	Frequency	Sample	Income	Frequency	Sample	Income	Net Benefits
Under $6,000	36	22.4	1.6	23	14.3	2.4	13.4
6,001–8,000	12	29.6	4.3	13	22.4	5.0	20.9
8,001–10,000	10	35.8	7.2	11	29.2	7.9	31.9
10,001–13,000	17	46.3	13.5	14	37.9	12.5	45.2
13,001–16,000	17	56.8	21.3	21	50.9	21.3	54.5
16,001–20,000	22	70.4	33.7	26	67.1	34.7	67.3
20,001–25,000	15	79.6	44.4	18	78.3	46.2	82.3
25,001–50,000	20	92.0	64.0	22	91.9	66.9	94.6
Over 50,000	13	100.0	100.0	13	100.0	100.0	100.0
Gini coefficient		0.514			0.450		

Note: Distribution based on actual CLCA benefits and net taxable family income, excluding nonsubchapter S corporations.

At the other extreme, the two highest income groups ($8,001–10,000 and $10,001–13,000) rereceiving 53.8% of the income but only 17.7% of the net CLCA benefits. The three middle groups with income in the $13,001–25,000 range received benefits that were approximately in the same proportion as their income and size. They received 33.7% of the income and 37.1% of the net benefits, while comprising 40.4% of the sample.

A comparison of the preprogram to postprogram income distribution indicates that the impact of the CLCA benefits in changing overall income distribution is substantial (see table 1). Net CLCA benefits were 39.7% of the total postprogram income of the lowest income category. As a result of the benefits received by the lowest income category, the number of families in this category dropped by 36% (from thirty-six to twenty-three). Income received by the lowest 22% of the population increased as a result of CLCA participation from 1.6% to 5.0% of total income, and the share received by the lowest 30% of the population increased from approximately 4.5% to 7.9%. The Gini coefficients declined from 0.514 for the preprogram distribution to 0.450 for the postprogram distribution.

Analysis of Within-Subgroup and Between-Subgroups Results

Of the 161 noncorporate survey respondents, 92 identified their principal occupation as farmer or farm manager, 45 as unrelated to farming, 16 as retired, and 8 failed to indicate their occupation. The 61 nonfarmers and retirees accounted for 39.6% of the CLCA contract holders and 25.7% of the net CLCA benefits.

A comparison of the farmers with all other respondents ("nonfarmers") revealed that the preprogram average income of $23,357 for nonfarmers is considerably higher than the farmers' average income of $16,873.[9] In addition, the preprogram income distribution shows a considerably greater degree of inequality for the farmer subsample, as reflected in a Gini coefficient of 0.537 compared with 0.463 for the nonfarm sample (tables 2 and 3).

In terms of the distribution of benefits, it is seen (tables 2 and 3) that for both subcategories the proportion of net benefits received by the lower income groups is greater than their proportion of preprogram total income. For the farmers, the lowest 25.0% receive only 6.4% of the income but receive 20.4% of the net CLCA benefits. Lower income categories are even more favored in the nonfarmer group, with the lowest 27.9% receiving 39.0% of net CLCA benefits, while receiving only 7.7% of the total income. Although conclusions should be approached with caution because of the small number of observations in the lowest income categories, the results of this survey show that for both subgroups a relatively higher proportion of benefits are received by the low-income categories.

Changes in the distribution of income as a result of the CLCA are very different between

[9] Removal of the eight persons not indicating their occupation from the nonfarmer subsample has virtually no impact on the income distribution.

Table 2. Pre- and Postprogram Income Distribution, Farmer Subsample, 1973 Survey

	Preprogram			Postprogram			
		Cumulative Percentage of			Cumulative Percentage of		
Income Range	Frequency	Sample	Income	Frequency	Sample	Income	Net CLCA Benefits
Under $6,000	25	26.9	1.9	13	14.1	2.6	10.4
6,001–8,000	8	35.5	5.4	10	25.0	6.4	20.4
8,001–10,000	8	44.1	9.9	9	34.8	10.8	32.2
10,001–13,000	7	51.6	15.1	6	41.3	14.5	47.2
13,001–16,000	10	62.4	24.2	12	54.4	23.9	55.6
16,001–20,000	11	74.2	36.4	14	69.6	37.5	67.2
20,001–25,000	6	80.6	44.7	9	79.4	48.3	85.1
25,001–50,000	12	93.5	67.7	13	93.5	71.3	95.6
Over 50,000	6	100.0	100.0	6	100.0	100.0	100.0
Gini coefficient		0.537			0.446		

Note: Distribution based on actual CLCA benefits and net taxable family income, excluding nonsubchapter S corporations.

the two groups. For the farmer respondents, the impact of the CLCA benefits on changing overall income distribution is quite large in comparison with the nonfarmer sample. The 26.9% of the population in the lowest income category (under $6,000) for the farmer sample received only 1.9% of the income prior to the program, whereas after the program only 14.1% of the population remained in this category; yet this smaller percentage received 2.6% of total income. By contrast, although only 14.8% of the nonfarmer population was in this category before the program, 13.1% still remained after the program, and the increase in their portion of total income was from 0.9% to only 1.9%.

The differential shift in income distribution for the two subsamples is reflected in the Gini coefficients reported in tables 2 and 3. For the farmer subsample, the change in distribution is most notable, with a drop in the postprogram Gini coefficient of 0.091. For nonfarmers the decrease was only 0.018. In absolute terms, average income increased under the program by $2,934 for the farmers and only $1,666 for nonfarmers to a level of $19,807 and $25,023, respectively. Thus, the differential impact of the preprogram versus postprogram benefits for the farmer and nonfarmer groups is found to bring the two groups closer together both in terms of absolute income and the equality of income distribution. The shift in income dis-

Note: Distribution based on actual CLCA benefits and net taxable family income, excluding nonsubchapter S corporations.

tribution among all respondents noted earlier can be attributed almost entirely to changes in distribution within the farmer subsample.

When the results of the eleven nonsubchapter S corporations (6.4% of all respondents) were examined, it was found that only 6.5% of net CLCA benefits were received by this category. Thus, even with the inclusion of nonsubchapter S corporations, the results of our 1973 survey of Sacramento County still support the conclusion that the effect of the CLCA is highly favorable to the lower income respondents.

Concluding Comments

Historically, national income redistributive programs have encountered difficulty in achieving their goals (Lane). Farm programs, often with explicit distributional goals, have encountered similar difficulty in effecting a change in the proportion of income received by low-income farm families (Bonnen, Schultze). Given the historic difficulties of redistributional programs and the previous criticism of the distributional impacts of the CLCA (Fellmeth), it was anticipated that the present study would provide a refinement of previous research in documenting the extent of concentration of program benefits among higher income farm entities. The results of our study were contrary to those expectations. For Sacramento County, the percentage of CLCA benefits obtained by corporations is small. Among all individual and subchapter S corporate respondents, the distribution of benefits is strongly in favor of the lower income groups. Furthermore, this redistributive effect is of sufficient magnitude, particularly among farmers, to cause a substantial change in the Gini coefficient.

The present study does not, however, invalidate the Fellmeth findings with respect to absolute levels of benefits received by the largest beneficiaries of the program. Thus, public policy makers may still wish to impose size of payment, size of enrollment, or residency restrictions on CLCA participation to achieve an even more favorable income distribution. Care should be taken in generalizing the Sacramento County results to other areas, and the rather high taxable family income levels among all respondents dampen the conclusions somewhat. However, our results indicate it is incorrect to single out the CLCA as contributing to a worsening of income distribution within agriculture. To the contrary, distributional impacts of the program appear to be highly favorable to lower income farmers.

Timber Management Decision Making under Imperfect Capital Markets

Paul A. Murphy, James C. Fortson, and James E. Bethune

Capital market imperfections seldom have been considered in the choice of financial criteria for making timber management decisions. A forest planning model for evenaged timber management is developed to evaluate criterion selection under imperfect markets. Some investment rules are shown to be equivalent to maximizing the firm's liquidation value for certain capital market conditions. Although imperfect capital markets severely limit wealth accumulation, small deviations from the optimal harvesting schedules do not severely affect the firm's value. Much concern about criterion selection would evaporate if the firm's investing and financing functions were integrated into a single process.

Key words: dynamic programming, forest investment, investment criteria, rotation age.

Assuming perfect markets in capital theory allows derivation of simple, elegant solutions to optimal intertemporal resource allocation, but no theory exists to handle capital budgeting problems when imperfect capital markets are encountered. Under a perfect capital market, adopting a strategy that maximizes the criterion "net present value of the firm" is equivalent to maximizing the economic welfare of the firm's owners. In imperfect markets this equivalence does not necessarily hold, and the problem of determining an acceptable financial decision-making criterion arises.[1]

Both net present value and internal rate of return have been proposed as criteria for making decisions in forest management, but relating criterion selection to imperfect capital markets has been rarely considered. This study is a first attempt to incorporate imperfect capital markets into a forest planning model using dynamic programming.

Past Work

Usually the primary investment goal is to maximize utility from consumption or to maximize wealth (Hirshleifer). Wealth maximization implies that accumulation is the ultimate goal of economic activity; utility maximization implies that consumption is the ultimate goal. Under perfect capital market conditions, maximizing net present value results in maximum utility because consumption and investment decisions can be made independently (Hirshleifer). However, in imperfect capital markets, investment and consumption decisions, in general, must be made jointly. Joint consideration requires a utility function, and since utility is difficult to quantify, utility maximization is of more theoretical than practical usefulness.

Most financial studies in forestry have dealt with wealth maximization, specifically with criterion selection for determining optimal rotation length. Gaffney, Goundry, and Bentley and Teeguarden stated that the return to the fixed factor should be maximized in rotation length selection. If the firm's land base is fixed, net present value is the correct criterion. If capital is fixed, internal rate of return is correct. Lippman proved that, with certain restrictions, investing in the project with the highest internal rate of return maximizes cash on hand at the end of a finite planning period. His restrictions allow neither consumption nor borrowing during the planning period.

Fortson investigated how adopting either net present value or internal rate of return affected optimal harvesting schedule and resultant flow of cash and wood from an industrial forest property. He postulated that inter-

Fortson is an associate professor in the School of Forest Resources, University of Georgia; and James E. Bethune is the chairman of the Department of Natural Resources, University of Connecticut.

[1] As used here, a criterion is a mathematical transformation on the revenue and cost stream of an investment. An investment rule utilizes the computed value of a criterion to determine the acceptability of an investment.

nal rate of return is the preferable criterion if the firm is expanding, whereas net present value is preferable if the firm is of constant size.

Capital rationing is a common market imperfection that has been studied in the capital budgeting literature. Weingartner used mathematical programming for selecting investment projects that are subject to capital rationing and other restrictions.

Maximizing return to a fixed factor as a guide to criterion selection is inadequate. Land and capital can be fixed simultaneously. Often neither is fixed. Furthermore, use of net present value implies that a perfect capital market exists in which funds can be lent or borrowed at the discount rate. Use of internal rate of return implies no capital market transactions, an infinite supply of forest land with the same productivity, and continued expansion of the enterprise (Bentley and Teeguarden). Hirshleifer pointed out the use of the internal rate of return implies infinite future value of the firm, hardly a reasonable assumption.

These two situations—a perfect capital market and no capital market—are extremes not encountered in practice. Either the amount of money that can be borrowed or lent is restricted in some way, or a multiplicity of lending and borrowing rates occur. What is the appropriate criterion for these situations? Our objective is to provide insight into this question.

Scope and Plan of Study

To judge the suitability of investment criteria, the concept of a globally optimal policy—the strategy that maximizes liquidation value at every point in time—is first developed.

Liquidation value of the enterprise is defined as the market value of the firm's assets at a particular time. Liquidation value in this sense is a measure of wealth. If a strategy maximizes wealth at every point in time, it is independent of the planning horizon. Independence is tested by ascertaining whether the optimal strategy varies with changes in length of the planning horizon.

Finite planning horizons are used in this study. Independence is determined by examining the optimal strategy for every planning horizon up to a specified maximum. The maximum time horizon used here is 100 years. If they do not vary, it is assumed that the optimal strategy is independent of the planning horizon and is a globally optimal policy.

Maximizing liquidation value is a constrained extremum problem falling within the province of mathematical programming. Dynamic programming is especially suitable because, in the course of obtaining an overall solution, the strategy for maximizing liquidation value in each intervening year of the planning period is also determined. In this study, dynamic programming models are developed for scheduling timber harvest and determining optimum size of the land base for an evenaged forest. The solutions generated by each model are analyzed to determine whether they are globally optimal and to investigate effects of adopting nonoptimal strategies in imperfect markets.

Assumptions are that the firm sells pulpwood on the open market and that any amount of bare land can be bought or sold for a constant price per acre. All land is managed identically. Regeneration costs and annual costs are constant per unit of land area. Harvested areas are successfully regenerated in the year of harvest. The only restrictions imposed on the investment decisions are those inherent in the choice of a finite planning period and in the imperfect market conditions examined. No constraints are imposed on wood flow.

The effect of choice of investment rule is investigated for (*a*) a forest enterprise operating under a perfect capital market and with a constant land base. Results for that case are then compared with those from (*b*) no capital market, variable land base; (*c*) absolute debt limit, variable land base; (*d*) internal generation of funds, variable land base; (*e*) maximum debt-equity ratio, variable land base; and (*f*) divergent lending and borrowing rates, variable land base. Of these, only the dynamic programming formulations of cases (*a*), (*b*), and (*f*) are presented here. Some implications of the results from other imperfect capital market cases are discussed. These examples are an intermediate step between assumption of a perfect capital market and the uncertainty that pervades capital budgeting in practice.

Procedures and Results

Perfect Capital Market, Constant Land Base

Liquidation value is maximized for a forest enterprise practicing evenage management on

one acre of forest land and operating under a perfect capital market. Annual costs are not included in the formulation, as they are considered fixed and not subject to managerial control. The firm's opportunities are to grow timber or to lend money at the current interest rate i. The initial endowment is $\$g_0(t_0)$. If the firm grows timber, it incurs a land cost of $\$b$ and a regeneration cost of $\$c$. If the initial endowment is insufficient to pay expenses, the balance can be borrowed at interest rate i compounded continuously. The expected yield in cords in t_j years is $y(t_j)$ at stumpage value per cord p.[2] Only one initial stocking level is considered. Liquidation value after one rotation is the value of the stumpage, the endowment, and accumulated interest:

$$(1) \quad py(t_1) + b + g_0(t_0)e^{it_1} - be^{it_1} - ce^{it_1}.$$

Let

$$(2) \quad g_k(t_k) = py(t_k) + b - ce^{it_k} - be^{it_k}, \qquad k = 1, \ldots, n,$$

then equation (1) can be rewritten as

$$(3) \quad g(t_1) + g_0(t_0)e^{it_1}.$$

Assuming that $g_0(t_0) = 0$, the maximum liquidation value at the end of the first rotation is

$$(4) \quad f_1(t) = \max_{\{t_1\}}\{g_1(t_1)\}.$$

The alternatives at the end of the first rotation are invest all the endowment at the external rate or invest in another timber rotation and lend the balance of the endowment at the market rate of interest. If the total endowment is invested at the external rate, the newly acquired revenue is

$$(5) \quad g_1(t_1)e^{it_2}.$$

If a second rotation is undertaken, the net revenue received at its end is

$$(6) \quad py(t_2) + b - ce^{it_2} - be^{it_2} + g_1(t_1)e^{it_2},$$

or

$$(7) \quad g_2(t_2) + g_1(t_1)e^{it_2}.$$

The maximum liquidation value for two rotations at the end of t years is the maximum of equations (5) and (7), or

$$(8) \quad f_2(t) = \max_{\{t_1,\, t_2\}} \{g_2(t_2) + g_1(t_1)e^{it_2},\ g_1(t_1)e^{it_2}\}.$$

[2] The form of this function is determined from Bennett and Clutter for planted slash pine, site index 80 (base age 25), 500 trees per acre.

Equation (8) is used to derive a recurrence relation between $g_1(t_1)$ and $g_2(t_2)$. No matter what the allocation t_2, the remaining years in the planning period $t - t_2$ must be optimally allocated to the first rotation. The optimal allocation of $t - t_2$ to the first rotation is $f_1(t - t_2$. Therefore,

$$(9) \quad f_2(t) = \max_{\{t_2\}} \{g_2(t_2) + f(t - t_2)e^{it_2}, f_1(t - t_2)e^{it_2}\}.$$

Dropping the assumption that $g_0(t_0) = 0$, let $g_0(t_0)$ be any constant and let

$$(10) \quad f_0(t) = \max \{g_0(t_0)\}.$$

We want to find the maximum liquidation value of the firm at the end of a finite planning period of t_{max} years, where n is the maximum number of rotations. The general recurrence relation is

$$(11) \quad f_k(t) = \max_{\{t_k\}} \{g_k(t_k) + f_{k-1}(t - t_k)e^{it_k}, f_{k-1}(t - t_k)e^{it_k}\}, \ k = 1, \ldots, n$$

subject to the restriction

$$(12) \quad 0 \le t_0 + t_1 + \ldots + t_n \le t_{max}.$$

Equation (11) is solved using the following values: $y(t_j) = e^{5.46096 - 28.15438/t_j}$, $i = 0.06$, $t_{max} =$ 100 years, $p = \$8$, $c = \$20$, $b = \$171.91$, and $f_0(t) = \$171.91$. The initial endowment $f_0(t)$ equals the land value, as it is assumed the firm owns the land at the beginning of the planning period.

The number of rotations for a problem is not usually known in advance, but an optimal solution is insured by setting the number of rotations considered larger than the number expected in the solution. Seven rotations are specified in the example.

The optimal strategy for a planning period of 100 years is to manage a sequence of five eighteen-year rotations, then sell the land in the ninetieth year, and invest the proceeds at the market rate of interest (table 1). For planning periods of less than 100 years, the general optimal strategy is to grow timber for the maximum number of eighteen-year rotations that can be subsumed by the planning period, sell the land immediately after harvesting the last rotation, and invest all proceeds at the market rate of interest for the rest of the planning period. This strategy holds for any planning period and thus is globally optimal.

The globally optimal policy can be inter-

Table 1. Optimal Strategy for the Perfect Capital Market, Constant Scale Problem

Rotation Number	Rotational Length[a] (Years)	Terminal Year in Planning Period	Liquidation Value of the Firm ($)
1	18	18	507
2	18	36	1,494
3	18	54	4,399
4	18	72	12,955
5	18	90	38,150
6	10z	100	69,513
7	—	—	—

[a] The letter "z" following the rotation length indicates that all the endowment is invested at the market rate of interest.

preted as managing the sequence of eighteen-year rotations that can be subsumed by the planning period, then selling the land, and investing the endowment at the interest rate for the remainder of the planning period.

A globally optimal policy is thus shown to exist. Any investment rule that leads to its adoption must be the best rule for the perfect capital market. Because

$$t_1 + t_2 + \ldots + t_n = t_{max}, \tag{13}$$

this problem can be changed to a net present value one by multiplying by the constant $e^{-it_{max}}$. Since this constant has no effect on the optimal policy, maximizing net present value is equivalent to maximizing liquidation value and is, therefore, the best investment rule.

The market value of the land is equal to the present worth of all future incomes expected to emanate from it. The effect of variations in the land's market price on the optimal policy can be observed by changing land value to $100 per acre. The resulting optimal strategy (table 2) then differs from that selected when land value equals the capitalized value of future income flows (table 1). Moreover, a change in planning period length results in a changed optimal strategy. Hence, there is no globally optimal policy. Conversely, if the market value exceeds net discounted value, timber growing would be uneconomic. The land would be sold, and the proceeds would be lent at the market rate of interest.

Table 2. Optimal Strategy for the Constant Scale, Perfect Capital Market Problem with a Reduced Land Value

Stage Number	Policy[a] (Years)	Year in Planning Period	Liquidation Value of the Firm ($)
1	18	18	435
2	18	36	1,422
3	18	54	4,327
4	19	73	13,683
5	20	93	45,591
6	7z	100	69,389

[a] If the letter "z" follows the policy number, all the endowment is invested at the market rate of interest.

This result implies that, at least for the production opportunities and capital markets examined here, liquidation value of the assets must equal the present worth of their future income flows for a globally optimal policy to exist. By being contained in the market value of the asset, cash flows subsequent to the planning horizon are introduced implicitly. This implied introduction of infinite flows makes the optimal strategy independent of time, so that it is unaffected by planning period length.

Constant Returns to Scale, No Capital Market

We now turn to the case in which returns to scale are constant but there is no capital market. With no capital market, timber management must be financed entirely from the firm's endowment and internal rate of return is the correct criterion, as shown by Boulding, Bentley and Teeguarden, and Lippman. Therefore, the maximization of internal rate of return is investigated first to insure that it is amenable to solution.

In addition to the variables defined for the first case, let x_j be acres owned during the jth rotation, and a be annual costs per acre. Because timber management must be financed solely from the firm's endowment, the amount of land that can be financed for the first rotation is determined by dividing the endowment by the per acre cost for a rotation of t_1 years, or

$$x_1 = f_0(t)/[b + c + at_1], \tag{14}$$

where $f_0(t)$ is a constant. The net revenue received by the firm at the end of the first rotation is

$$x_1[py(t_1) + b]. \tag{15}$$

The amount of land that can be financed for the second rotation is the revenue from the first rotation divided by the per acre cost for the second:

$$x_2 = x_1[py(t_1) + b]/[b + c + at_2], \tag{16}$$

or, in general,

$$x_{k+1} = x_k[py(t_k) + b]/[b + c + at_{k+1}], \quad k = 1, \ldots, n-1. \tag{17}$$

If a perfect capital market exists, the net revenue received by the firm from timber growing at the end of the kth rotation would be

$$h_k(t_k,x_k) = x_k[py(t_k) - ce^{it_k} + b - be^{it_k} - a\int_0^{tk} e^{iu}\,du]. \tag{18}$$

It follows that liquidation value of the firm at the end of a planning period, t_{max} years in length, with n rotations would be

$$L(t,x) = h_1(t_1,x_1)e^{i(t_{max}-t_1)} + h_2(t_2,x_2)e^{i(t_{max}-t_1-t_2)} + \ldots + h_n(t_n,x_n)e^{i(t_{max}-t_1-\ldots-t_n)}. \tag{19}$$

To maximize internal rate of return, equation (19) first must be set equal to zero. Moreover, the problem is further constrained by equations (14) and (17) and consequently is a constrained extremum problem:

$$\max i \tag{20}$$

subject to the restrictions

$$x_1 = f_0(t)/[b + c + at_1], \tag{21}$$

$$L(t,x) = 0, \tag{22}$$

and

$$x_{k+1} = x_k[py(t_k) + b]/[b + c + at_{k+1}]. \tag{23}$$

Maximizing internal rate of return subject to these restrictions is a nonlinear programming problem. No method of solution is found.

The problem can be simplified considerably by excluding annual costs. With regeneration cost of \$$c$ per acre and land purchase price of \$$b$ per acre, the maximum amount of land that can be financed for the first rotation is

$$x_1 = f_0(t)/(b + c). \tag{24}$$

The value of the firm after the first rotation is

$$h_1(t_1) = x_1[py(t_1) + b]. \tag{25}$$

The amount of land that can be financed for the second rotation is

$$x_2 = h_1(t_1)/[b + c]. \tag{26}$$

Because there are no transaction costs, it is assumed that all land is sold at the end of a rotation and repurchased for the next rotation, thereby simplifying the formulation. The net worth at the end of the second rotation is

$$h_2(t_2) = x_2[py(t_2) + b] = f_0(t)[py(t_1) + b][py(t_2) + b](b + c)^{-2} \tag{27}$$

Let

$$g_k(t_k) = [py(t_k) + b]/[b + c], \quad k = 2, \ldots, n. \tag{28}$$

Therefore, the firm's value after the kth rotation is

$$f_0(t)g_1(t_1)g_2(t_2) \ldots g_k(t_k). \tag{29}$$

Liquidation value at the end of a finite planning period is

$$H(t) = f_0(t)g_1(t_1) \ldots g_n(t_n), \tag{30}$$

subject to

$$t_1 + t_2 + \ldots + t_n \leq t_{max}. \tag{31}$$

During intermediate rotations, all cash proceeds are immediately expended for the subsequent rotation; thus, the only net cash flows are initial and terminal amounts. Discounted proceeds and outlays are equated by

$$f_0(t) = f_0(t)g_1(t_1) \ldots g_n(t_n)e^{-i(t_1+\ldots+t_n)} = 0. \tag{32}$$

Solving for i,

$$i = \ln[g_1(t_1)g_2(t_2) \ldots g_n(t_n)]/[t_1 + t_2 + \ldots + t_n]. \tag{33}$$

Because the rotation lengths must sum to t_{max},

$$i = \ln[g_1(t_1)g_2(t_2) \ldots g_n(t_n)]/t_{max}. \tag{34}$$

Because $1/t_{max}$ is constant, maximizing the expression

$$\ln[g_1(t_1)g_2(t_2) \ldots g_n(t_n)] \tag{35}$$

maximizes i. Moreover, values of t_j, $j = 1, \ldots, n$, that maximize equation (30) are invariant under the logarithmic transformation. Therefore, maximizing internal rate of return is equivalent to maximizing liquidation value. The development of the dynamic programming recursion formula is straightforward. Equation (30) is maximized subject to restriction (31).

The optimal allocation to the first rotation is

$$f_1(t) = \max_{\{t_1\}} \{g_1(t_1)f_0(t - t_1)\}, \tag{36}$$

where $f_0(t - t_1)$ is a constant. The optimal allocation to the first two rotations is

$$(37) \quad f_2(t) = \max_{\{t_1,t_2\}} \{g_2(t_2)g_1(t_1)f_0(t - t_1)\}.$$

Applying the principal of optimality, no matter what the allocation t_2 is, allocation of the remaining time to the first rotation is optimal. Equation (37) in general becomes

$$(38) \quad f_k(t) = \max_{\{t_k\}}\{g_k(t_k)f_{k-1}(t - t_k)\}, \quad k = 1, \ldots, n.$$

Table 3 contains a solution for equation (38), where $y(t_k) = e^{5.4098-28.15438/t_j}$, $p = \$8$, $b = \$25$, $c = \$20$, $f_0(t) = \$1{,}000$, $t_{max} = 100$ years, and $n = 8$.

The results show liquidation value maximized when individual rotation lengths are nearly equal. For example, the optimal strategy for a planning period of ninety-five years is (14, 13, 14, 14, 14, 13, 13, 0). However, because rotation lengths vary with change in planning period length, a globally optimal policy does not exist.

The remaining models to be explored are more realistic than either the perfect capital market or no capital market case. They represent conditions frequently encountered in practice. Further algebraic formulations and dynamic programming solutions are omitted except in the last example.

Absolute Debt Limit

Imposition of a capital market imperfection limiting the amount of borrowing to $20,000 is studied. As in the no capital market case, land base is treated as a variable. Stumpage price varies inversely with increasing size of land base. This situation may exist where there is only one large primary processing plant, such as a pulpmill. Since there is only a single market, and stumpage price is a residual, the price declines as transport distance to the processing facility increases.

Table 3. Optimal Strategy for the Constant Returns to Scale, No Capital Market Problem

Stage Number	Policy (Years)	Year in Planning Period	Liquidation Value of the Firm ($)
1	14	14	6,155
2	15	29	42,834
3	15	44	298,070
4	14	58	1,834,730
5	14	72	11,293,429
6	14	86	69,515,133
7	14	100	427,890,760
8	—	—	—

The optimal strategy adopted shows that for the first forty-nine years the firm's expansion is limited by the limit on debt. However, with each rotation the firm generates more capital to finance the next rotation. By the end of the third rotation, the firm generates enough capital so that debt limit no longer restricts expansion of the land base. Subsequent land base sizes are optimal for the rotation length selected.

The problem is then resolved with the debt limit restriction lifted to ascertain how severely the debt limit reduces liquidation value. Optimal policies with and without the debt limit are similar, but imposition of a debt limit reduces liquidation value 78% and thus adversely affects wealth accumulation. The optimal strategy changes slightly with changed length of planning horizon, so no globally optimal policy is demonstrated.

Internal Generation of Funds

In this formulation, investments are limited to those permitted by funds generated within the timber management operation. The problem is a special case of the debt limit problem in which debt is restricted to zero. With debt financing prohibited, the capital market imperfection operates more restrictively than in the debt limit problem. Not until the eighty-first year are sufficient funds generated to deactivate the capital market restriction. Eliminating debt financing causes a 95% drop in liquidation value as compared with a perfect capital market solution. As in the previous solution, changes in the planning horizon result in slight changes in the optimum rotation lengths; therefore, no globally optimal policy is determined.

Maximum Debt-Equity Ratio

In this formulation, the amount borrowed is limited by a maximum allowable ratio of debt to equity. Such a limitation arises in several ways. The firm may adopt such a policy to protect the value of its stock, or lenders may impose such a limitation to insure loan recovery in the event of dissolution of the firm. The debt assumed is the discounted costs of the

rotation minus the current endowment. The equity is the market value of land holdings. For this solution, the maximum debt-equity ratio is set at 0.5. Permissible debt increases as the endowment increases. Timber management operations are limited by the debt-equity restriction for the first sixty-one years. After the fourth rotation, the restriction is no longer active. This restriction reduces liquidation value by 93%.

Differing Lending and Borrowing Rates

We now turn to the last and most realistic model. Usually, lending and borrowing rates of interest differ. We assume that although there is a divergence of rates, the firm can lend at the rate i_1 and borrow at i_2 without restriction as to amount; also, $i_2 > i_1$.

When both lending and borrowing occur within the same rotation, the model becomes a dynamic programming problem with three state variables. No suitable method was found to solve the three state variable case, so a simplification is employed to make the problem amenable to solution. As in the no capital market case, the source of difficulty is the inclusion of annual cost. Consequently, annual costs are deleted. The following equation is the value of a timber rotation t_k years in length and x_k acres in size:

$$(39)\quad g_k(t_k,x_k,i_k) = x_k\,p(x_k)y(t_k) + b - ce^{i_k t_k} - be^{i_k t_k};\ i_k = i_1,\ i_2.$$

The interest rate is now a variable.

The dynamic programming problem contains three state variables, but x_k and i_k may be determined as follows. The firm, if possible, will try to make the size of the land base optimal. Let x_{k2}^* be the root of the equation.

$$(40)\quad \partial g_k(t_k, x_k, i_2)/\partial x_k = 0.$$

Since the second derivative of equation (39) with respect to x_k is negative, the function is a maximum at x_{k2}^*. Hence, the optimal scale size for a fixed t_k would be x_{k2}^*. The optimal scale size for a fixed t_k would be x_{k2}^* when money is borrowed.

If

$$(41)\quad x_{k2}^*(b + c) \geq f_{k-1}(t-t_k),$$

money is borrowed and $x_k = x_{k2}^*$. However, if

$$(42)\quad x_{k2}^*(b + c) \geq f_{k-1}(t - t_k),$$

then the rotation can be financed entirely from internally generated funds. Let x_{k1}^* be the root of the equation

$$(43)\quad \partial g_k(t_k,x_k,i_1)/\partial x_k = 0.$$

If

$$(44)\quad x_{k1}^*(b + c) \leq f_{k-1}(t - t_k),$$

then scale size is not restricted by the endowment and $x_k = x_{k1}^*$. If inequality (44) is violated, then $x_k = x_{k1}^{**}$, where

$$(45)\quad x_{k1}^{**} = f_{k-1}(t - t_k)/(b + c).$$

The dynamic programming recursion formula becomes

$$(46)\quad f_k(t) = \max\{g_k(t_k, x_k, i_k) + f_{k-1}(t-t_k)e^{i_k t_k}, f_{k-1}(t-t_k)e^{i_1 t_k}\},\quad k = 1, \ldots, n.$$

Values of x_k and i_k are determined at each stage by fixing the value of t_k. The first expression in the recurrence relation is the value of investing in timber management. The second expression signifies that all the endowment is lent at the interest rate i_1.

Table 4 shows the optimal strategy of the differing lending and borrowing rates problem, where $y(t_k) = e^{5.46098-28.16438/t_k}$, $p(x_k) = \$(8 - 0.03\,x_k^{1/2})$, $t_{max} = 100$ years, $b = 25$, $c = \$20$, $i_2 = 0.10$, $i_1 = 0.06$, and $f_0(t - t_1) = 0$ (initial endowment).

For the first thirty-two years of the planning period, the firm finances timber management by borrowing. At the end of the second rotation, sufficient money is generated so that the firm is restricted by neither the divergent interest rates nor the size of the endowment. A globally optimal policy does not exist because a variation in planning period length changes the optimal strategy. With a planning period of ninety-five years, the optimal rotation lengths become t_{95} = (16, 16, 19, 19, 20, 5*, 0). The asterisk by the 5 indicates that all the endowment is invested externally for the last five years of the planning period.

How much does the gap in interest rates affect the liquidation value? Table 5 shows the optimal strategy for the case in which the interest rates are identical, $i_1 = i_2 = 0.06$. No other changes are made in the problem. The liquidation value in table 5 for the last year in the planning period represents the maximum value attainable. The results indicate that the divergent interest rates cost the firm about 64% of its potential value. If the divergence was less, this loss would be smaller.

Table 4. Optimal Strategy for the Different Lending and Borrowing Rates Problem with Decreasing Returns to Scale

Stage	Policy (Years)	Land (Acres)	Restriction Code[a]	Year in Planning Period	Liquidation Value of the Firm ($)
1	16	4,789	1	16	201,327
2	16	4,789	1	32	1,198,504
3	19	16,820	2	51	5,497,188
4	18	16,709	2	69	17,783,010
5	17	16,488	2	86	50,742,260
6	14	14,854	2	100	118,393,100
7	—	—	—	—	—

[a] If money is borrowed, the code is 1; if money is lent and the scale size is unrestricted, the code is 2.

The effect of following a nonoptimal policy can also be assessed. Assuming no divergence in interest rates, what would be the result of the firm managing a sequence of nineteen-year rotations, all 16,820 acres in size, and then investing the resulting endowment in year ninety-five of the planning period for the remaining five years? The liquidation value of this strategy would be $330,799,918. Thus, the percentage loss following this nonoptimal policy is minuscule.

Discussion and Conclusions

Extension of the forest planning model to include determining not only optimal rotation length but also optimal size of the forest land base poses no conceptual difficulty. A change in rotation length produces a fairly large modification in the forest land base, indicating that the optimal size may be sensitive to changes in other variables.

An important finding is that liquidation value is relatively insensitive to small deviations from the optimal strategy. Consequently, the forest manager can vary harvesting schedules somewhat without significantly affecting liquidation value.

Comparison of liquidation values obtained when constraints such as debt limit are imposed or not imposed on the models show that the presence of market imperfections limits the firm's wealth accumulation. The severity of this limitation depends on the type of imperfection and the degree by which it deviates from the perfect capital market.

Equivalence of maximum liquidation value with other investment rules has been demonstrated for the perfect capital market case and the no capital market case. Equivalence can also be shown for the remaining cases in a similar manner.

The maximum liquidation value problem may be transformed to one of maximum net present value by multiplying by the constant e^{-it} for the following problems: absolute debt limit, internal generation of funds, and maximum debt-equity ratio. This transformation is suitable for these problems because the sum of the optimal rotation lengths in all cases is equal to the length of the finite planning horizon. Because the transformation is a constant, it has no effect on optimal strategy.

The different lending and borrowing rates problem is more complex. A simple transformation does not exist because the effective rates of interest are determined in the course

Table 5. Optimal Strategy for the Decreasing Returns to Scale Problems with No Capital Market Restrictions and Annual Costs Excluded

Stage	Policy (Years)	Land (Acres)	Restriction Code[a]	Year in Planning Period	Liquidation Value of the Firm ($)
1	19	16,820	0	19	1,749,743
2	19	16,820	0	38	7,220,783
3	19	16,820	0	57	24,327,453
4	19	16,820	0	76	77,816,103
5	21	16,783	0	97	276,342,658
6	3	0	9	100	330,842,185
7	—	—	—	—	—

[a] If investment is made in timber management, the code is 0; if all the endowment is invested at the external rate, the code is 9.

of solving the problem and cannot be determined a priori. Nevertheless, this problem too may be transformed to a net present value problem with no effect on the optimal strategy. The solution for the maximum net present value problem is identical to the one for maximum liquidation value.

A globally optimal policy is demonstrated to exist only for the perfect capital market case. The distinguishing features of this problem are the presence of a perfect capital market and a pricing of the firm's assets, particularly land, that reflects the assets' income-producing potentials. Thus, these income flows are implicitly introduced into the problem.

The equivalence of the market value and the capitalized value of an asset becomes more unlikely under imperfect capital markets. For example, in the different lending and borrowing rates problem, the present value of an asset's income stream is calculated using an interest rate that depends upon the amount of the firm's accumulated wealth. Thus, the prospect of the market price of land coinciding with its value to a firm is unlikely. The conditions necessary for the existence of a globally optimal policy are, therefore, quite demanding.

Because use of the globally optimal policy to find a "best" criterion is limited in application, forest managers are still faced with the problem of criterion selection. Much concern about the choice of financial criteria, however, would evaporate if the financing functions and investment functions are integrated into a single decision-making process—usually using mathematical programming. The cost of capital then becomes part of the analysis, and opportunity costs can be evaluated using the dual variables of the mathematical programming model. Capital budgeting models found in the literature (e.g., Weingartner) and the simple models formulated in this study demonstrate how the financing and investment functions can be integrated. This integration represents the next logical step in the evolution of timber management planning.

Portfolio Adjustments: An Application to Rural Banking

Lindon J. Robison and Peter J. Barry

A general method is provided for evaluating how an expected-utility-maximizing choice is changed in response to factors shifting the mean-variance (EV) efficient set and changes in the decision maker's level of risk aversion. Substitution and income effects under uncertainty are defined, related to those existing under certainty, and analyzed graphically and in a quadratic programming model of a rural bank. The bank application includes risk and liquidity components and indicates that the magnitude of the portfolio response may not be trivial. Evidence is also provided indicating the consistency between bank behavior and the EV decision criterion.

Key words: expected utility, portfolio theory, risk, rural banking.

Numerous studies in decision making under risk have focused primarily on generating information needed to identify an initial expected-utility-maximizing choice from a mean-variance (EV) efficient set. Such studies have sought better ways to order portfolios into efficient and inefficient sets and better ways to measure probability distributions and utility functions (Dillon). However, much less attention has been given to evaluating the response of the expected-utility-maximizing choice to changes in decision parameters that shift the EV set (Tobin, Cass and Stiglitz, Levy, Adler, Royama and Hamada). Because this response may be significant, there is a need to develop a conceptual framework and empirical methods for predicting equilibrium adjustments under uncertainty.

This paper provides a general method for evaluating how an expected-utility-maximizing choice is changed in response to factors shifting the EV set and changes in the decision maker's level of risk aversion. The following sections define appropriate measures of risk aversion and shifts in the EV set caused by changes in the probability distribution of returns on risky assets, changes in returns on safe assets, and changes in initial wealth. The substitution and income effects under uncertainty are defined, related to those existing under certainty, and analyzed both graphically and in a quadratic programming model of a representative rural bank. The bank example demonstrates that the magnitude of the portfolio response may not be trivial and should be the subject of further empirical analyses. The paper concludes with a review of various approaches for evaluating the consistency between bank behavior and the EV decision criterion.

Risk Aversion Measures

Consider a decision maker choosing among risky alternatives with outcomes expressed by probability distributions. Assume further that his utility function for wealth $U(Y)$ reflects diminishing marginal utility for increases in wealth. This condition describes a risk averter, an individual who requires an expected return on a risky asset in excess of the returns on a safe asset in order to be indifferent toward investment in the two assets. This difference—a risk premium—decreases as the investor becomes less risk averse. The degree of risk aversion is exhibited in two measures formulated independently by Arrow and Pratt to allow interpersonal comparisons of risk aversion at particular wealth levels: $R_a(Y) = -U''(Y)/U'(Y)$ = absolute risk aversion, and $R_r(Y) = -YU''(Y)/U'(Y)$ = relative risk aversion.

Each measure implies different responses of risk aversion to changing levels of wealth. Consider the following results for a decision maker who can allocate his wealth between a risky and a safe asset. If the amount of wealth invested in the risky asset increases (decreases) with wealth, the investor has decreasing (increasing) absolute risk aversion. If the proportion of wealth invested in the risky asset increases (decreases) with wealth, the investor has decreasing (increasing) relative risk aversion.

In the analysis to follow the direction of portfolio adjustments on the EV frontier is related to measures of increasing, constant, or decreasing absolute risk aversion ($R'_a(Y) \gtreqless 0$). Empirical observation by Arrow and by others strongly supports an assumption of decreasing absolute risk aversion. Hence, the absolute measures permit a fairly general yet definitive treatment of portfolio responses. Empirical evidence on relative risk aversion is less definitive. Arrow, for example, provides a theoretical argument with some empirical support for increasing relative risk aversion. More recent studies (Cohn et al., Friend and Blume) provide evidence supporting both decreasing and constant relative risk aversion.

Shifts in EV Sets

To begin the discussion of shifts in EV sets, the following definitions are offered. A negative (positive), nonparallel shift in the EV set occurs if lines drawn tangent to the EV sets at points of equal variance form a smaller (larger) angle of inclination with the abscissa, the axis measuring expected wealth. A parallel shift in the EV set occurs if lines drawn tangent to the EV sets at points of equal variance form the same angle of inclination with the abscissa.

Nonparallel shifts are caused by changes in expected returns or variance of a risky asset(s) and by changes in returns of a safe asset(s). Shifts to the right are illustrated in figure 1. The nonparallel shifts induced by changes in the distribution of risky assets do not change the point of intersection of the EV frontier with the axis measuring expected wealth. In contrast, nonparallel shifts induced by changes in returns of a safe asset do change the point of intersection.

Suppose, for example, that the expected return on a risky asset increases. Since this increase permits a higher level of expected terminal wealth with the same variance for all portfolios holding the risky asset, the new EV frontier resulting from the increased returns lies to the right of the initial frontier, and the slope of the tangent line at the point of equal variance declines. A negative, nonparallel shift to the right is also caused by a reduction in the variance of a risky asset. The reduction in asset variance implies a higher level of expected terminal wealth for the same level of portfolio variance or, alternatively, a lower level of variance for the same level of terminal wealth. In a similar fashion, positive, nonparallel shifts to the left of the EV frontier result from increases in the variance or decreases in the expected returns on risky assets. Finally, increases in the expected return on a safe asset cause positive, nonparallel shifts to the right of the EV frontier, while decreases in the return on a safe asset produce negative shifts to the left.

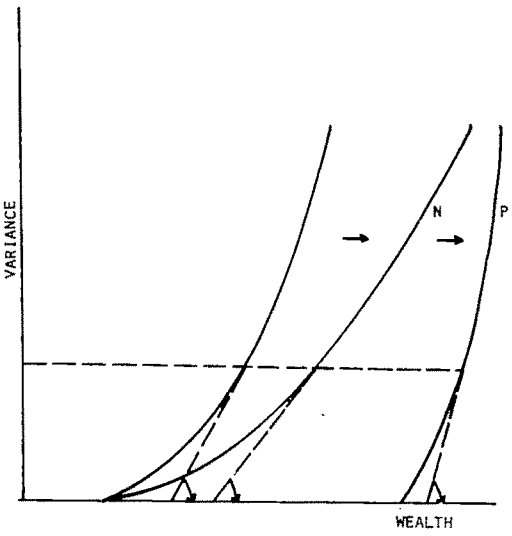

Figure 1. Negative (*N*) and positive (*P*) nonparallel shifts

Parallel shifts in the EV frontier are caused by changes in the decision maker's initial wealth. Adding risk-free wealth increases expected terminal wealth by equal amounts for each portfolio in the original EV set, leaving their variances unaffected. Hence, the EV frontier shifts right with tangent lines at points of equal variance exhibiting the same slope.

The Income Effect

Under conditions of certainty, a change in demand for an asset resulting from an increase

in real income with prices held constant is defined as an income effect. Under uncertainty, however, prices of assets are random variables, and to identify the income effect their distributions are assumed to remain constant as risk-free wealth increases. Thus, the income effect under uncertainty is the change in demand for an asset resulting from an increase in risk-free wealth while holding probability distributions constant and is expressed by a parallel shift in the EV frontier.

Continuing the analogy under certainty, an increased, decreased, or constant demand for an asset resulting from an increase in risk-free wealth identifies an asset as normal, inferior, or neutral, respectively. Under uncertainty, if the equilibrium variance on the new EV frontier has increased, decreased, or remained constant following a parallel shift to the right, then the demand for the risky assets has changed accordingly, and they may be considered as normal, inferior, or neutral assets, respectively.

The kind of income effect occurring under conditions of uncertainty is related to measures of absolute risk aversion by the following theorem (Cass and Stiglitz): if there are two assets, one risky and one safe, total purchases of the risky asset increase, remain constant, or decrease with increase in initial wealth as absolute risk aversion decreases, remains constant, or increases.

The separation property defined by Tobin permits extension of the analysis from a two-asset to a general (n-asset) model, provided one of the assets is risk free. Tobin shows that the desired combination of risky assets along an EV set is independent of the amount invested in the safe asset. Therefore, all relevant portfolio choices along an EV set can be provided by varying the amount invested in a risk-free asset and the amount invested in a fixed combination of the risky assets. This separation property permits the utility-maximizing choice from an EV set to be considered as a choice between one risky asset and one risk-free asset.

Hence, the Cass and Stiglitz theorem implies that, for choices among $n - 1$ risky assets and one safe asset from an EV set, the income effect for the $n - 1$ risky assets is positive, zero, or negative as absolute risk aversion decreases, remains constant, or increases. Corollary 1 can now be derived: if there are n assets with at least one risk free and if the expected-utility-maximizing choice occurs from an EV set, then an increase in risk-free wealth increases, leaves unchanged, or decreases the equilibrium slope on the new EV frontier for decreasing, constant, or increasing absolute risk aversion, respectively.

To prove this corollary, recall that an increase in risk-free wealth produces a parallel shift to the right in the EV set. By definition, the slopes at points of equal variance on parallel EV curves are the same and can vary only by changing the purchases of risky assets. The Cass and Stiglitz theorem together with Tobin's separation property require that for increases in risk-free wealth purchases of the $n - 1$ risky assets increase, remain constant, or decrease for decreasing, constant, or increasing absolute risk aversion, respectively. Therefore, the equilibrium slope on the new EV set increases, remains constant, or decreases, respectively, for decreasing, constant, or increasing absolute risk aversion.

These results indicate that risky assets are normal goods for investors with decreasing absolute risk aversion, neutral goods for investors with constant absolute risk aversion, and inferior goods for investors with increasing absolute risk aversion. In a similar fashion, if an increase in risk-free wealth yields no additional purchases of risky assets, then holdings of safe assets must increase. Hence, safe assets are normal goods for investors with constant or increasing absolute risk aversion and may be normal, inferior, or neutral goods for investors with decreasing absolute risk aversion.

The Substitution Effect

Under conditions of certainty, the substitution effect is the change in demand for an asset resulting from a change in relative prices after compensating the decision maker for a change in real income. Under uncertainty, the substitution effect is defined as the change in quantity demanded resulting from a change in the probability distribution of prices after compensating the decision maker for a change in risk-free income.

The substitution effect for adjustment in EV efficient portfolios is illustrated in figure 2. Let the initial equilibrium occur at point A on EV frontier 1. Since the exact shape of the indifference curve causing the equilibrium at point A is uniquely determined by each decision maker's utility function, one can approximate

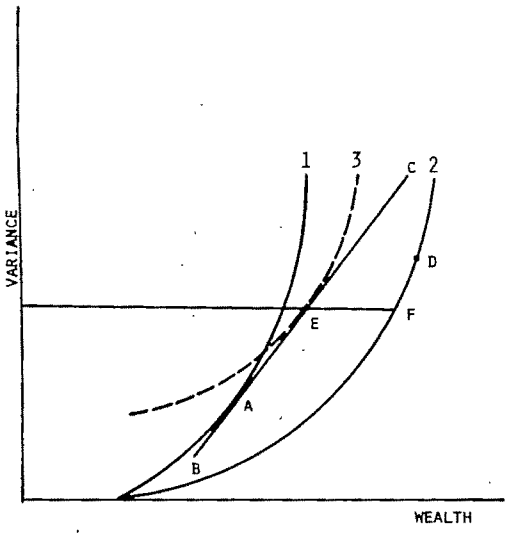

Figure 2. Income and substitution effects

the indifference curve by the straight line BC drawn tangent to point A. Let the EV frontier exhibit a negative, nonparallel shift to the right caused by a reduced variance or by an increased expected return on a risky asset. Further, let the decision maker's new equilibrium occur at point D on EV frontier 2. To identify the substitution effect, the decision maker is compensated for his increase in real income by a parallel shift of EV frontier 2 to the left until a new tangency occurs at point E between the compensated EV frontier 3 and straight line BC, which approximates the decision maker's initial indifference curve. The substitution effect is the difference in the quantity of assets held in portfolios A and E. The income effect explains changes in the quantity of assets arising from the movement from portfolio E to D. The portfolios E and F have the same variance and thus the same amount of risky assets. The income effect for risky assets between E and F is therefore zero and can only be nonzero if the slope on the new EV frontier changes. Hence, the change in the amount of risky assets is the same whether the adjustment occurs from A to E or from A to F.

Any change in the quantity of risky assets that occurs while holding the equilibrium slope of the EV frontier constant is due entirely to the substitution effect. Any change in the quantity of risky assets that occurs when the slope changes is due entirely to the income effect. For safe assets, the income effect expressed by parallel shifts in the EV frontier while holding the equilibrium slope constant is not zero but is equal to the difference of the increase in expected wealth and the change in the holdings of risky assets.

How the equilibrium slope on the new EV frontier changes from the initial equilibrium depends on the decision maker's measure of absolute risk aversion. The results are expressed in corollary 2: if the expected-utility-maximizing choice occurs from an EV set and the indifference curve is approximated by a linear tangent to the EV set, then for any shift to the right (left) the equilibrium slope increases (decreases), remains constant, or decreases (increases) as there is decreasing, constant, or increasing absolute risk aversion.

To prove corollary 2, recall that for nonparallel shifts the substitution effect is identified as the movement between the tangency of the linear approximation of the indifference curve with the original EV frontier and its tangency with the compensated EV frontier. The slopes at these two tangency points are equal. Since the compensated EV frontier and the new EV frontier are parallel, movements from one to the other involve adjustments to parallel shifts. From corollary 1 it is known that, for parallel shifts to the right, the purchase of risky assets and hence the equilibrium slope increases, remains constant, or decreases for decreasing, constant, or increasing absolute risk aversion, respectively. Hence, the result of corollary 2 is proved.

The adjustments in equilibrium slopes to changes in risk aversion and shifts in EV frontiers have the following effects on portfolio wealth and variance. Increases in initial wealth as expressed by parallel shifts cause equilibrium variance to increase, remain constant, or decrease as there is decreasing, constant, or increasing absolute risk aversion. Expected wealth increases for decreasing or constant absolute risk aversion and may increase or decrease for increasing absolute risk aversion depending on the magnitude of the income effect.

For negative, nonparallel shifts to the right, expected portfolio wealth and variance increase for decreasing or constant absolute risk aversion. This result follows from the earlier definitions that indicate that a portfolio on the new EV frontier with the same variance has a smaller slope and only by increasing the variance can a slope be obtained that equals or exceeds the slope of the initial portfolio.

Similarly, for positive, nonparallel shifts to the right, the equilibrium variance decreases for constant or increasing absolute risk aver-

sion. Again, the definitions imply that for positive shifts a portfolio on the new EV frontier with the same variance has a greater slope and only by decreasing the variance can a slope be obtained that is less than or equal to the slope of the initial portfolio. Analogous responses can be derived for leftward shifts in the EV frontier.

To this point, the analyses of income and substitution effects associated with shifts in EV sets have been expressed in terms of their effects on equilibrium slopes and on total wealth and variance of the portfolios. Extending the adjustment theory to evaluate holdings of individual assets requires further mathematical development and is treated in detail by Robison. It can be shown, for example, that an individual asset's substitution effect is directly related to changes in its expected return and inversely related to changes in its variance. Increases in both an asset's expected return and its variance would therefore tend to be offsetting. More complicated relationships exist for substitution effects caused by changes in covariances and by changes in expected returns and variances of other assets.

Portfolio Adjustments and Rural Banking

The portfolio adjustment process is illustrated in a risk programming analysis of a rural bank that typically allocates part of its loans to financing agriculture. Rural banks are generally small in size and often experience special liquidity problems arising from seasonal flows of loans and deposits. They also experience rather high risks in agricultural lending due primarily to variability in farmers' incomes and limited opportunities for asset diversification. These conditions have prompted much concern with the ability of rural banks to cope with these risk and liquidity problems and still offer adequate loan services to their customers (Federal Reserve Board of Governors 1975). One approach to studying these problems is through the use of bank models that include risk and liquidity components. Including these components permits more thorough and accurate evaluation of a bank's portfolio responses to changes in loan risks, liquidity needs, costs of funds, and other factors.

A representative model bank for southeastern Texas is used as a basis for formulating the risk programming model. Assets in its balance sheet total nearly $25 million with equity capital of $1.2 million, a loan to deposit ratio of 0.55, and a loan to capital ratio of 10.42. The model is developed for relatively easy adaptation to banks of different size, type, structure, location, and other such characteristics. The general properties of the model are summarized below, while additional information on bank theorems, model structure, and data is found in Robison.

The mean-variance criterion assumes that the decision maker's expectations are formulated in terms of normal distributions that are fully specified by means and variances or that his utility function is quadratic, reflecting preferences only toward means and variance of expected returns. We assume that the banker's expectations on wealth are normally distributed, hence restricting his expected-utility-maximizing choice to an EV set. The banker's ordinal utility function is then approximated for a given level of utility by the negative exponential $U(Y) = 1 - e^{-aY}$, where $a > 0$. The negative exponential implies linear indifference curves between means and variances that are consistent with the linearity assumed in deriving the substitution effect. Freund has shown, for example, that maximizing the expected value of the negative exponential integrated over a normal density function is equivalent to maximizing $E[U(Y)] = W - a\sigma^2/2$. Multiplying through by $\lambda = 1/a$ yields $E[U(Y)] = \lambda W - \sigma^2/2$. Parameter λ identifies the optimal EV choice by expressing the desired trade-off or equilibrium slope between variance (σ^2) and expected wealth (W) for the given level of utility.[1]

The initial EV set is derived with a quadratic program specified to identify bank portfolios with minimum variance for alternative levels of expected wealth for a three-month period. The bank's decision variables include choices in lending and in purchasing securities, acquiring deposits, borrowing, and paying taxes and dividends. Net earnings from these activities add to bank wealth. Risk is introduced as variance-covariance entries for

[1] Strictly interpreted, the negative exponential utility function as expressed above with linear mean-variance indifference curves implies constant absolute risk aversion. Allowing λ to vary with different levels of expected utility produces a set of nonparallel linear indifference curves that approximate the actual indifference curves only in the neighborhood of the tangency with the EV frontier. Extending the nonparallel linear indifference curves much beyond this neighborhood eventually leads to their intersection, thereby violating the indifference feature. However, this analysis assumes that variations in λ do model the income effect for investors with different degrees of risk aversion and that any intersection of indifference curves does not occur near the tangency point.

expected returns on loans and for liquidity risk, reflecting linkages between the stochastic demand for cash from deposit variability and capital gains and losses arising from liquidation of one-year and two-year bonds prior to maturity. Three-month bonds have no liquidity risk and are specified as safe assets with zero variance. Annual expected rates of return, variances, and covariances for these investments are reported in table 1.[2]

One EV efficient solution is selected as the bank's utility-maximizing choice in order to serve as the basis for rerunning the quadratic program to observe portfolio adjustments to changes in deposit costs, expected rates of return, variances, loan-deposit feedback rates, and risk aversion. Holding λ constant as other parameters are changed produces portfolio adjustments reflecting the substitution effect for risky assets. Allowing λ to vary introduces the income effect.

Quadratic programming results for changes in these parameters are reported in table 2 for activities entering the EV efficient solutions. Column 1 reports parameter values and activity levels for the initial solution. Column 2 indicates model results for increasing deposit costs, equivalent to a decline in risk-free wealth. A decline in risk-free wealth causes a parallel EV shift to the left, while holding λ constant implies a zero income effect and constant risk aversion. Constant absolute risk aversion implies that risky assets are neutral goods that do not change with wealth. The model's purchases of risky assets and equilibrium variance remain constant. However, expected terminal wealth decreases with the decrease in wealth.

Column 3 combines increasing deposit costs with a declining slope. Decreasing λ for a parallel shift to the left implies decreasing absolute risk aversion, a decline in the purchase of risky assets, and a decrease in equilibrium variance and expected terminal wealth. In turn, purchases of safe assets increase.

Column 4 introduces an increased rate of return on agricultural loans resulting in a negative, nonparallel EV shift to the right. Holding λ constant requires that both variance and expected terminal wealth increase in order to achieve the new equilibrium. The new equilibrium contains increased purchases of agricultural loans and reduced purchases of safe assets.

Column 5 reflects a reduction in the deposit feedback on real estate loans causing, in effect, a reduced rate of return on that asset. The result is a positive, nonparallel EV shift to the left. As expected, results respond in a manner opposite to those of column 4. Holding λ constant requires a decrease in equilibrium variance and expected terminal wealth. The purchase of real estate loans declines as does that of agricultural loans—a complementary asset.[3]

[2] Expected net returns on loans are estimated from the 1970 through 1972 quarterly *Functional Cost Analysis* reports for a rural bank in central Texas (Federal Reserve Bank of Dallas). Variances and covariances reflecting default risk and variations in lending costs are calculated as deviations from a regression of net loan returns with time as the independent variable. Lending incurs no liquidity risk, since sales of loans prior to maturity are not permitted.

Estimates of expected net returns on securities are obtained from historical data published in the *Federal Reserve Bulletin* (Federal Reserve Board of Governors 1970–72). Securities are assumed to be coupon bonds bought at par with fixed quarterly interest payments. Risk on securities is attributed solely to their likelihood of sale prior to maturity to meet stochastic demands for cash at values that may vary with changes in market interest rates. This liquidity risk is reflected by variances and covariances of expected returns on securities that are derived statistically from a time series of quarterly bond values from 1970 through 1972 and weighted by an assumed probability of liquidation. Finally, covariances among expected returns on loans and securities are assumed to be zero.

[3] Under certainty two assets are complementary if an increase in returns on one increases the demand for the other. Under risk and for investors with constant or decreasing absolute risk aver-

Table 1. Annual Expected Net Returns and Variances and Covariances for Bank Investments

	Agricultural Loan	Real Estate Loan	Installment Loan	1-Year Bond	2-Year Bond	3-Month Bond
				%		
Expected net returns	6.92	6.20	4.88	5.30	5.86	4.66
Variances and covariances						
Agricultural loan	0.400	−0.038	0.134	0	0	0
Real estate loan	−0.038	0.328	0.356	0	0	0
Installment loan	0.134	0.356	0.468	0	0	0
1-year bond	0	0	0	0.228	0.024	0
2-year bond	0	0	0	0.024	0.324	0
3-month bond	0	0	0	0	0	0

Table 2. Results of Quadratic Programming Model of a Commercial Bank for Selected Parameter Changes

	Model					
Parameters	1	2	3	4	5	6
Equilibrium slope (λ)	5,654	5,654	5,500	5,500	5,500	5,500
Deposit cost (%)	4.80	5.00	5.00	5.00	5.00	5.00
Rate of return—agr. loan (%)	6.92	6.92	6.92	6.96	6.96	6.96
Feedback—real estate loan	0.2	0.2	0.2	0.2	0.05	0.05
Variance—agr. loan (%)	0.4	0.4	0.4	0.4	0.4	0.5
Quarterly results ($1,000)						
Expected wealth	1,280.2	1,280.1	1,279.4	1,279.8	1,279.2	1,278.9
Variance	180,288.7	180,288.7	176,511.0	178,545.9	175,975.8	174,227.4
Purchase risky assets						
Real estate loan	340.1	340.1	340.1	340.1	126.9	115.2
Agricultural loan	626.7	626.7	398.4	522.1	501.9	400.6
Purchase safe assets						
3-month bond	3,290.0	3,290.0	3,488.3	3,380.8	3,557.6	3,656.8
Ending cash	7,648.8	7,648.6	7,789.2	7,713.0	7,873.5	7,946.5

Column 6 reflects results of an increased variance on agricultural loans generating a positive, nonparallel EV shift to the left. As in column 5, a positive, nonparallel EV shift to the left while holding λ constant requires that equilibrium variance and expected wealth both decline. The solution contains reduced purchases of risky assets and increased purchases of safe assets.

EV Analysis and Bank Behavior

The predictive ability of portfolio adjustment theory presumes, of course, that the decision maker—the rural banker, in this case—behaves according to the assumptions underlying the theory. These assumptions include those of ordering, continuity, and independence, which underlie expected utility theory (Dillon), the distinction between risky and safe assets, and the responses of absolute risk aversion to changing wealth. Moreover, utility estimation using the mean-variance criterion also requires the normality or quadratic utility assumptions discussed earlier.

The restrictiveness of the mean-variance assumptions has been seriously criticized (Borch, Feldstein). Assuming normality may be inappropriate for many investment situations, although in this analysis assuming normality and linear indifference curves to approximate the expected-utility-maximizing choice from the EV set is judged to be less restrictive than assuming quadratic utility. Quadratic utility functions must clearly be used with care because they eventually exhibit declining total utility as wealth increases and they imply portfolio adjustments consistent with increasing absolute risk aversion, results that seem inconsistent with commonly observed risk behavior. Still, the severity of these mean-variance restrictions is not fully resolved. Tsiang, for example, has demonstrated the general applicability of the EV criterion as long as the portfolio risk, expressed by the ratio of variance to mean expectations, is small relative to the expected value of returns. This general applicability of the EV criterion together with its mathematical convenience have contributed greatly to its extensive use in empirical research.

Nonetheless, despite the extensive use, there is still need to evaluate whether or not decision behavior appears consistent with the EV criterion. Consider, for example, the effect on a rural bank's portfolio of increased risk on agricultural loans, a commonly observed condition in the early 1970s (Barry and Fraser). Riskier agricultural loans imply greater difficulties in debt servicing and greater likelihood of loan default with both conditions reflected in EV analysis by increased variance on agricultural loans. Portfolio adjustment theory together with risk programming results suggest reduced holdings of agricultural loans as well as other complementary assets. Confirming this result in terms of actual bank behavior involves the use of one or more approaches to empirical observation of bankers' preferences, performance, or

sion, two assets are complementary if an increase in the expected returns on one increases the demand for the other or if an increase in the variance of one decreases the demand for the other.

both. Several of these approaches to empirical observation are briefly reviewed.

Consider first an evaluation of bankers' responses to loan risk through review of periodic banker surveys of credit conditions and financial outlook. These surveys are designed in part to elicit the lender's expectations on credit responses to changes in a number of decision parameters. Presumably, these expectations are used in managing the bank's portfolio and thus are reflected in actual decision making. Numerous lender surveys are currently used, and many include questions on the lender's response to changing loan risks. An example is a survey conducted by the American Bankers Association and made available to the U.S. Department of Agriculture for the 1975 *Agricultural Finance Outlook*. Bankers were asked to identify their responses if farm lending were to become more risky. Possible responses included reduction in the volume of farm lending and increases in interest rates, security requirements, and degree of supervision of farm loans.

Only the volume response is specified in the portfolio adjustment theory. However, it seems reasonable to expect that lenders may utilize one or more of the other risk responses instead of or in addition to the volume response. Indeed, only 38 of 119 lenders responding to the question indicated a likely reduction in farm lending, while 24 even indicated an increase in farm lending. However, cross-checking of answers for other risk responses confirms their use as substitute responses. As an example, of the 81 bankers who would not reduce farm lending, 48 reported that they would increase interest rates on farm loans as a risk response. In addition, 108 bankers indicated they would increase security requirements on farm loans, and 111 indicated an increase in loan supervision. Hence, these results appear generally consistent with the results of portfolio adjustment theory, although a wider range of risk responses was permitted in the survey.

A second approach to empirical testing consists of a simulated borrowing and interview approach to measure the bankers' credit responses to changes in loan risk. Barry and Willmann use this approach in evaluating lender responses to alternative levels of forward contracting by crop producers. They observe that the contracting strategy most preferred by the sample of lenders generates about 17% more total credit and about 53% more crop credit than the lenders' least preferred strategy. This observation is consistent with the portfolio adjustment indicated here in that increased risk on agricultural loans would reduce their level in the bank's portfolio of risky assets.

A third approach that could be used to observe bank behavior is analysis of historical financial data in order to relate the responses of various bank portfolio holdings to changes in expected risk, returns, and wealth. While balance sheet and income data are available for individual U.S. banks (Federal Reserve Board of Governors 1976), the data still only indicate the jointly occurring effects of banker's decisions and numerous other factors that influence the portfolio composition. Hence, the data only provide limited insight on actual bank decisions. It would be difficult, in the case of rural banks, to identify and measure the joint effects of changes in interest rates, the money supply, general price levels, deposit composition, reserve and other legal requirements, bank charter and management, loan demand and lending competition, and risk responses by borrowers, all of which interact with changing loan risk to explain observed portfolio adjustments. Nonetheless, developing procedures for measuring these joint effects appears to be a fruitful area for further research.

Another approach to observing behavioral preferences is through the derivation of expected utility functions for individual rural bankers. These utility functions would identify the properties of an expected distribution of returns that are relevant to the banker and would help value the risk parameter together with its response to changing wealth. Increasing experience has been gained in deriving expected utility functions. Empirical evidence in the case of farmers, for example, indicates that expected utility theory likely explains farmer behavior more accurately than profit maximization (Lin, Dean, and Moore). However, little evidence can be found on the derivation of utility functions for rural bankers or on utility responses over time to changes in decision parameters.

There is also concern with the appropriateness of distinguishing between risky and safe assets. However, this distinction in commercial banking is in accordance with commonly used practices. Crosse and Hempel review the

various approaches to assessing the adequacy of bank capital and indicate the various risk classes of bank assets. Risk-free assets are normally considered to be cash balances, short-term government securities, federal funds sold, and other assets of high quality and short maturity. While these assets may experience small degrees of market risk, they are generally considered to be virtually riskless. Other bank assets are considered risky with the risk expressed by variances and covariances as outlined earlier.

Concluding Comments

The portfolio adjustment framework developed in this paper extends the firm's equilibrium analysis to conditions of uncertainty. The distinction of income and substitution effects associated with shifts in EV frontiers and changes in risk aversion provides a stochastic counterpart to predicting equilibrium adjustments under conditions of certainty. This extension should enhance the predictive ability of expected utility theory assuming, of course, that the decision maker behaves according to the premises of the theory. While several approaches to behavioral observation are reviewed, it is clearly an area for further empirical analysis.

In terms of methodology, the portfolio adjustment framework explicitly introduces risk as a behavioral influence and broadens the kinds of sensitivity analyses that can be used in evaluating equilibrium adjustments. The rural bank example demonstrates the need to model risk and liquidity components for more complete evaluation of the bank's responses to factors causing changes in its risks, liquidity, and profitability. Indeed, a number of current policy issues in rural banking may significantly affect bank risk and liquidity—government guarantees of farm loans, secondary markets for farm loans, changes in bank borrowing privileges, adoption of variable interest rates, and interest-bearing demand deposits. However, the portfolio adjustment framework also adds complexity to problem identification, model specification, data needs, and empirical verification. In the bank example, careful attention would be needed to properly identify and measure the effects of each policy issue on the distribution of returns for risky assets, changes in returns on safe assets, and changes in wealth, together with their effects on risk aversion. These remain as challenging tasks.

Measurement of Capacity Depreciation Based on Engineering Data

John B. Penson, Jr., Dean W. Hughes, and Glenn L. Nelson

The widely used estimates of annual capacity depreciation for selected types of farm producer capital published by the USDA rest on the assumption that the amount of capital consumed annually equals a constant fraction of the existing capital stocks. This study demonstrates, through the use of agricultural engineering data, that the productive capacity of farm tractors deteriorates in a concave rather than the convex pattern suggested by present USDA estimates. The implications for studies estimating aggregate production functions based on factor shares or farm investment demand equations are discussed. Finally, recommendations for change to selected sector economic accounts are made.

Key words: capacity depreciation, embodied technical progress, physical deterioration, real productive value, vintage.

Studies that have estimated aggregate farm production functions based on factor shares or have tested hypotheses related to the aggregate investment behavior of farm production sector participants generally utilize the capital stock and depreciation data series published by the U.S. Department of Agriculture (1975a, b). These studies require an accurate measure of the annual depreciation of the productive capacity of farm capital and net additions to this capacity if they are to avoid inconsistent parameter estimates. An accurate measure of capacity depreciation is also important to public acceptance of the USDA's widely followed net farm income series (1975b). Their estimate of annual depreciation, defined as that "estimated outlay, in current prices, which would be required if farmers were to replace the plant and equipment used up during the year," is an important component of the farm production expenses data series used to residually estimate net farm income (1969, p. 10). Finally, the relevance of the USDA's estimate of net investment in farm plant and equipment as an indicator of current farm business expansion requires an accurate measure of capacity depreciation (1975b). Thus, it is of considerable importance that these capital stock and depreciation data series reflect as closely as possible the actual losses in the productive capacity of farm capital.

Many researchers may not be aware that these data series are approximated by a procedure that assumes that the amount of capital consumed during production is equal to a constant fraction of the existing capital stock. This assumption suggests, for example, that the greatest single annual loss in the productive capacity of a farm tractor resulting from physical deterioration is realized in its first full year of use, the second greatest annual loss in its productive capacity in its second full year of use, etc. The adoption of this approximation procedure, according to Ott, Ott, and Yoo, is normally defended on the grounds that "capital is utilized more intensively and therefore consumed more rapidly during the early part of its service than during the latter part" (p. 112). Yet, is this assumption realistic for producer goods such as farm tractors, planters, and other farm production machinery whose annual use is limited by the biological nature of farm production and by existing plant size? In addition, what is the effect of embodied technical progress associated with new producer goods on the productive capacity of the existing capital stock? While this approxima-

tion procedure may be convenient in many respects, a review of literature provides little empirical evidence to support it.

This study illustrates the potential measurement error associated with the present procedures used by the USDA to approximate the capacity depreciation of farm capital. Initially, the capacity depreciation pattern implied by the USDA procedures and those suggested recently by Coen are examined. Information on postponed repairs and maintenance, accumulated use, and downtime from a recent agricultural engineering survey is then used to measure a capacity depreciation pattern for tractors purchased during 1948–74. The capital stocks and flows suggested by this pattern are then compared with those published for farm tractors by the USDA. Finally, the implications of these findings for further research are discussed.

Alternative Approximation Procedures

The existing capital stock and capital flows such as depreciation that account for changes in this stock between accounting dates can be valued in three different ways: current market value, book value, and productive value. Aside from capital sales or transfers to other sectors, the current market value of the existing stock of capital declines as economic depreciation, or loss in value, occurs during the year. Similarly, the book value of the existing stock of capital declines as tax depreciation is taken. The productive value of the existing stock of capital, on the other hand, is given by the present value of the flow of productive services it provides over the services lives of the different vintages of capital on farms.[1] Thus, when expressed in constant prices, the real productive value of the existing capital stock of farm tractors declines as physical deterioration occurs.

If firms behave as neoclassical investment theory suggests, their annual capital expenditures are influenced by the current productive capacity of their existing capital stock, while the level of firm output depends on the flow of productive services provided by capital, other things being constant. Thus, studies of aggregate production functions or investment behavior must relate to the real productive value of capital. The wisdom of using present USDA approximations of capital stocks and flows or those proposed recently by Coen in these studies must therefore depend on how accurately these data series reflect changes in the productive capacity of farm capital.

Procedure Used by the USDA

The *Balance Sheet for the Farming Sector* reports an estimate of the current market value of the existing stock of farm machinery and motor vehicles deflated by its own implicit price deflator (USDA 1975a). The unpublished estimate for the existing stock of farm tractors valued in 1967 prices is given by[2]

$$(1) \qquad K_t = (1 - 0.5\delta)I_{t-1} + (1 - \delta)K_{t-1},$$

where K_t is the current market value of the existing stock of farm tractors at the beginning of the year expressed in 1967 prices, while I_{t-1} is capital expenditures for farm tractors in the previous year, also expressed in 1967 prices (USDA 1971, p. 3). The value of δ chosen is that which reduces the original value of capital expenditures by 95% at the end of their assumed service life, implying a 5% salvage value (USDA 1969, p. 10). The USDA estimate of annual depreciation (D_t) for farm tractors published in *Farm Income Statistics* is equal, when expressed in 1967 prices, to

$$(2) \qquad D_t = 0.5\delta I_t + \delta K_t,$$

such that

[1] The current market value of farm tractors can differ from their productive value. While this phenomenon is typically observed in markets for used consumer goods such as automobiles, it seems somewhat paradoxical that a farm operator maximizing his expected utility would sell a producer good such as a farm tractor for less than its remaining productive value to the firm. Yet several hypotheses can be advanced as to why the current market price in secondary machinery markets can be less than its productive value to the firm. For example, a systematic negative bias is incurred if used tractor prices, particularly for those tractors traded in during the early stages of their service life after any warranties have expired, are used to value all tractors of identical size, technology, and age still on farms. This bias results from these tractors likely having a lower productive value than those retained on farms because they have either been used more than average or have not received normal repairs and maintenance. A second hypothesis is that the risk-averse farm operator assigns a greater weight to the likelihood of acquiring a tractor with less than average remaining productive value in secondary markets than he would to the likelihood of acquiring a tractor with greater than average remaining productive value. Thus, he discounts the price he would have been willing to pay if he had perfect knowledge of the tractor's remaining productive value. Finally, the farm operator may encounter less favorable financing arrangements with respect to the length of loan, the downpayment required, and interest rate charged on loans to purchase used machinery than available for loans to finance new machinery purchases, thereby depressing used tractor prices.

[2] The issue of accidental damage is ignored for the moment. This topic and the effects of downtime are treated in a later section.

$$N_t = K_{t+1} - K_t = I_t - D_t, \tag{3}$$

where the value of K_t is given by equation (1), while N_t represents annual net investment in farm tractors expressed in 1967 prices.

The principal source of embodied technical progress affecting the capacity of farm tractors during 1948–74 has been their increasing horsepower.[3] Since the USDA's implicit price deflator is weighted to account for prices paid for multiple size and type classes of farm tractors, the value for I_t used in equation (1) appears to adequately reflect the quality of farm tractors purchased in year t. The procedures used to approximate K_t and D_t given by equations (1) and (2) would suggest that the productive capacity of a farm tractor decays geometrically over its service life. While the depreciation pattern implied by this procedure may yield realistic estimates of economic depreciation, one would intuitively expect losses in the productive value of a farm tractor resulting from physical deterioration to be relatively small in the early stages of its service life. Due to a lack of evidence put forth by the USDA in support of its geometric decay capacity depreciation pattern for farm tractors, the advisability of using D_t as a measure of replacement investment or K_t as a measure of the real productive value of existing capital in aggregate investment behavior studies is open to question. The use of D_t when accounting for capital services in aggregate farm production functions based on factor shares must also be reconsidered.

Procedures Proposed by Coen

Based on the work of Solow, Coen recently examined several alternative capacity depreciation patterns for equipment and structures in the manufacturing sector. These patterns purportedly reflect the effects of alternative distributions of physical deterioration and embodied technical progress on the productive capacity of existing capital.

Coen's approximation procedures suggest that the real productive value of the existing stock of farm tractors according to the jth capacity depreciation pattern is given by

$$K_{jt} = \sum_{i=1}^{\infty} \left(1 - \sum_{k=1}^{i} d_{jk}\right) I_{t-i}, \tag{4}$$

such that the remaining fraction of the original productive capacity of farm tractors in the mth year after their original purchase is given by

$$1 - \sum_{i=1}^{m} d_{ji} = \left[\frac{1 - \sum_{i=1}^{m} h_{ji}}{(1+g)^m}\right]. \tag{5}$$

The h_{ji} weights reflect the fraction of the original productive capacity of farm tractors lost due to physical deterioration during the ith year after their original purchase according to the jth capacity depreciation pattern. This approximation of the existing capital stock suggests that the productive capacity of farm tractors approaches zero as the value of $\sum_{i=1}^{n} h_{ji}$ approaches one, where n denotes the end of the service life. The existing capital stock is reduced further according to the Solow-Coen aggregation theorem by the rate of embodied technical progress (g) associated with new farm tractors. This suggests that the productive capacity of the existing stock of farm tractors at the beginning of the year declines if new farm tractors are more efficient, other things being constant. Clearly, the productive capacity of the stock of farm tractors at the beginning of the year remains unchanged in this instance.[4]

Rather than assume that capacity depreciation is a constant fraction of the existing capital stock, Coen approximates replacement investment in the current year (R_t), assuming $d_{j0} = 0$, by

$$R_{jt} = \sum_{i=1}^{\infty} d_{ji} I_{t-1}, \tag{6}$$

where the d_{ji} weights are identical to those assigned to the deflated capital expenditure flows (I_t) in equation (4).[5] The real productive

[3] Other changes in technology include increased use of hydraulics, four-wheel drive, and tractor cabs. The authors are unaware of data on the effects of these innovations on the productive capacity of farm tractors. To the extent that these and other omitted technical improvements have increased the productive capacity of tractors and are not adequately reflected in the USDA's unpublished implicit price deflator, the estimate of I_t will be understated.

[4] The Solow-Coen aggregation theorem employs a sliding-scale procedure to account for technological obsolescence in the existing capital stock. Using this approach, previous vintages of farm tractors are discounted further by the current increase in efficiency units associated with new farm tractors. Two problems exist with this procedure. Initially, one could not compare the real productive values associated with the existing capital stock in 1970, for example, with that presently associated with the current capital stock. Further, the argument that the real productive value of existing tractors has declined simply because of an increase in the efficiency associated with new farm tractors has little intuitive appeal.

[5] The Solow-Coen approximation of replacement investment goes beyond the traditional concept of measuring capital used up

value of current net investment (N_t) is therefore given by

$$N_{jt} = K_{jt+1} - K_{jt} = I_t - R_{jt}. \tag{7}$$

The alternative paths taken by the capacity depreciation patterns examined by Coen are merely assumed to capture the effects of physical deterioration and technological obsolescence on the productive capacity of existing capital. Those patterns studied are (*a*) an infinite geometric decay pattern (GD-INF) that extends over an infinite time horizon, where $d_i = \phi(1 - \phi)^{i-1}$ and $\phi = 2/n$, (*b*) a finite geometric decay pattern (GD-FIN) that is truncated at the end of the assumed service life of the farm tractor, (*c*) a sum-of-the-years-digits pattern (SYD), where $d_i = (n + 1 - i) \Big/ \sum_{i=1}^{n} i$ for $i = 1, \ldots, n$, (*d*) a "one-hoss shay" pattern (OHS), where $d_i = 0$ for $i = 1, \ldots, n - 1$ and $d_n = 1$, and (*e*) a straight-line pattern (SL), where $d_i = 1/n$ for $i = 1, \ldots, n$. The fraction of the original productive capacity lost annually over the service life of the farm tractor implied by each of the above patterns is illustrated in figure 1.

The researcher adopting Coen's approximation procedures is faced with *j* net investment series that, in turn, necessitate testing *j* sets of hypotheses related to the aggregate investment behavior of farm production sector participants. Coen implies that the "right" pattern is that which yields the net investment regression with the lowest standard error of the estimate. In addition, several questions arise regarding the implications of those capacity depreciation patterns examined. The OHS capacity depreciation pattern, for example, assumes that annual repairs and maintenance restore the productive capacity of a farm tractor to its original level, that no repairs and maintenance are postponed in the latter years of its service life, and that the rate of embodied technical progress in farm tractors is equal to zero. The remaining patterns also suggest an unrealistic decline in the productive capacity of farm tractors and other farm production machinery over their service life. That the productive capacity of a farm tractor falls as fast or faster in the early years of its service life than it does in its latter years seems highly questionable. While the capacity depreciation patterns examined by Coen certainly define the upper and lower limits of study, they do not represent a realistic spectrum of possibilities. Surprisingly omitted from study to date has been the triangular area between the SL and OHS patterns in figure 1, which has the most intuitive appeal.

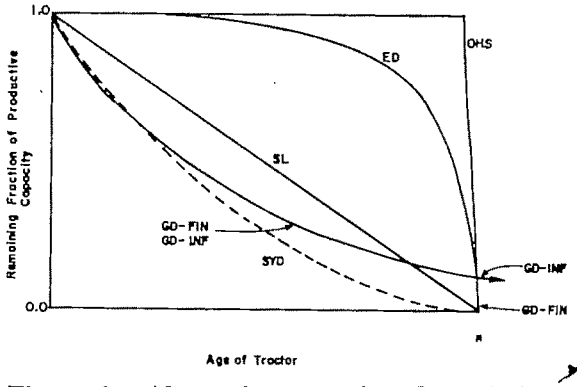

Figure 1. Alternative capacity depreciation patterns

Direct Measurement Using Engineering Data

Rather than assume one or more capacity depreciation patterns, one can instead utilize available engineering data on annual rates of physical deterioration and embodied technical progress to estimate the real productive value of capital stocks and flows; that is, engineering data can be used to estimate a pattern of d_i that, in turn, can be used to measure the real productive value of the existing stock of farm tractors and to partition net and replacement investment. As Griliches suggests, "we need to know the 'right' measure of capital in practice and how much difference it actually makes" (p. 205).

Proposed Measurement Procedure.

Based on a modification of Solow's original aggregation theorem, an alternative to equation (4) is proposed that allows the researcher to account for the specific influences that physical deterioration and embodied technical progress have upon the productive capacity of the existing stock of farm tractors. The real productive value of the existing stock of farm tractors is given by

$$K_t = \sum_{k=1}^{\infty}(1 - \sum_{i=1}^{k} h_i)I_{t-k}, \tag{8}$$

during current production or "keeping capital intact" by including technological obsolescence as well. Because of this, use of R_{jt} when estimating aggregate farm production functions based on factor shares results in measurement error, since R_{jt} measures more than just current capital consumption.

where we assume, as did Griliches, that I_t reflects the embodied technical progress (g) for tractors purchased in year t. As $\sum_{i=1}^{k} h_i$ approaches one, the remaining fraction of the original productive capacity of farm tractors purchased in year $t - k$ approaches zero. While some farm tractors may remain on farms beyond this point and have a positive salvage value, they will "fall out" of this measure of the real productive value of the existing stock.

Assuming for the moment that data are available to estimate a set of h_i weights for tractors, the procedure for measuring the real productive value of the existing stock of farm tractors given by equation (8) is preferred over that suggested by equation (1) in studies of aggregate investment behavior. Rather than assume the geometric decay capacity depreciation pattern to be true, equation (8) allows one to utilize estimates of the set of h_i weights based on microdata set analysis. Equation (8) is preferred over equation (4) as equation (8) specifically allows for a separate accounting of factors causing change to the productive capacity of the capital stock over time and narrows this focus to a single measure of the capital stock.

Given the assumption that annual capital expenditures for farm tractors valued in 1967 prices are an acceptable measure of the productive capacity of farm tractors when originally acquired, capacity depreciation for tractors on farms in year t expressed in 1967 prices is given by

$$D_t = \sum_{k=0}^{\infty} h_k I_{t-k}, \tag{9}$$

where

$$N_t = K_{t+1} - K_t = I_t - D_t. \tag{10}$$

As $\sum_{i=0}^{k} h_i$ approaches one, the original productive capacity of farm tractors purchased in year $t - k$ is entirely lost due to physical deterioration.[6] Thus, equations (9) and (10) express current capital expenditures for farm tractors in terms of their real productive value rather than current market value. This reflects the assumption that firms consider the relative efficiency of different vintages of farm tractors when restoring or expanding the productive capacity of their existing capital stock.

Estimation of Physical Deterioration

If θ_m represents the additional fraction of the original productive capacity of tractors requiring repairs and maintenance during the mth year and ξ_m represents that fraction of current and past physical deterioration not repaired during the mth year, then current needed repairs and maintenance expressed as a fraction of the original purchase in the mth year (NR_m) is given by[7]

$$NR_m = \theta_m + \sum_{i=1}^{m-1} \left[\prod_{j=1}^{i} \xi_{m-j} \right] \theta_{m-i}. \tag{11}$$

The first component (θ_m) represents the effect of current physical deterioration, while the second component represents the sum of postponed repairs and maintenance in previous years. Given equation (11), observed repairs and maintenance expressed as a fraction of the original purchase price in the mth year after its original purchase must equal

$$OR_m = (1 - \xi_m)\theta_m + (1 - \xi_m) \sum_{i=1}^{m-1} \left[\prod_{j=1}^{i} \xi_{m-j} \right] \theta_{m-i}, \tag{12}$$

or needed repairs and maintenance times the fraction not postponed. Solving for θ_m and reducing terms,

$$\theta_m = (OR_m)/(1 - \xi_m) - \xi_{m-1}((OR_{m-1})/(1 - \xi_{m-1})). \tag{13}$$

The set of h_i, defined earlier as the fraction of the original productive capacity lost due to physical deterioration during the mth year, is therefore given by

$$\sum_{i=0}^{m} h_i = \sum_{i=0}^{m} (\theta_i - OR_i), \tag{14}$$

which represents the numerator in the capacity depreciation pattern suggested by equation (9). This also implies that

[6] We assume, as did Coen, that the value of h_0 is independent of the calendar date at which the capital good was originally purchased. The effect of this assumption is negligible in the present study due to the concave shape of the ED pattern over the service life of farm tractors. The effect of this assumption is much greater in those studies that, like Coen, assume a geometric decay capacity depreciation pattern that is convex rather than concave to the origin.

[7] The original purchase price and observed annual repair and maintenance costs are expressed in constant rather than current dollars.

$$(15)\quad 1 - \sum_{i=0}^{m} h_i = 1 - ((\xi_m)/(1 - \xi_m))OR_m,$$

which represents the key piece of information needed to measure K_t in equation (8) when $h_0 = 0$. The capacity depreciation pattern for farm tractors suggested by equation (15) is a function of one observed variable (OR_m) and a behavioral assumption as to the manner in which needed repairs and maintenance are postponed by farm operators over the service life of the tractor (ξ_m).[8]

A recent survey by Hunt provides information on annual repairs and maintenance costs, annual amounts of use and the original purchase price for 745 farm production machines spanning the 1958–74 period. Hughes recently estimated the following polynomial relationship for those farm tractors in Hunt's survey for which a continuous record was maintained:

$$(16)\quad \sum_{i=1}^{m} OR_i = \underset{(0.0005)}{0.0047\ m^2} - \underset{(0.00008)}{0.0002\ m^3}, \qquad \bar{R}^2 = 0.53,$$

where the figures in parentheses are the standard errors of the coefficients.[9] Equation (16) reaches its maximum approximately sixteen years after the original purchase of the farm tractor. By this time, cumulative observed repairs and maintenance are almost 40% of the original purchase price. In addition, the inflection point is approximately eight years after the original purchase of the tractor. This suggests that maximum annual repair and maintenance costs, which total approximately 4% of the original purchase price, are incurred in the eighth year.[10] Importantly, the results found by Hughes can be used in this study to determine the numerator in equation (15).

Before we can use equation (15), however, we must examine the distribution of ξ_m over the service life of the farm tractor. Since this information is not available from Hunt's survey, annual values for ξ_m are derived based on hypothesized management behavior. To begin with, two things are known about its distribution: ξ_m is equal to one when OR_m is equal to zero, which was shown above to occur sixteen years after the original purchase of the tractor, and both ξ_m and $\sum_{i=1}^{m} OR_i$ reach their maximum in the same year. A review of literature also suggests potential characteristics regarding machinery management behavior. According to Bowers, "putting off repairs only leads to more serious problems, including a high percent of downtime and even higher repair bills" (p. 35). Thus, ξ_m is expected to be relatively small in the early years of the service life of the tractor. As the tractor becomes older and needed repairs and maintenance increase due to physical deterioration, ξ_m is likely to increase at an increasing rate up to a point where minimum repair and maintenance needs are met. At the point where no further repairs are made, ξ_m equals one.[11] Based on this assumed

[8] This equation does not reflect the impact of downtime incurred during normal production hours on the productive capacity of existing farm tractors. Downtime can occur due to physical deterioration associated with either accumulated use or accidental damage. Letting the right-hand side of equation (15) be represented by Γ_m, the effects of downtime in year m can be measured by

$$1 - \sum_{i=1}^{m} h_i = \Gamma_m(1 - \alpha_m),$$

where α_m is that fraction of the original productive capacity lost during the mth year after its original purchase due to downtime. Unfortunately, Hunt's survey provides only a limited number of cases where adequate information on downtime was kept. In those cases, the average downtime reported during normal production hours expressed as a fraction of downtime plus hours used was only 2.7%. Further, no particular relationship between α_m and m was evidenced. Since α_m refers to downtime during normal production hours, the argument that "the older a tractor is, the more time is spent on repairs" does not necessarily imply a greater amount of downtime. In view of this, the lack of any relationship between α_m and m appears less suspect.

[9] While one would expect difficulties in applying equation (16) at the micro level, it should be unbiased when applied to all farm tractors if Hunt's sample is representative of the total population. The relatively low coefficient of determination found by Hughes for equation (16) might be the result of regressing $1 - \sum_{i=1}^{m} OR_i$ on age (m) rather than cumulative hours of use, and the hypothesis of geometrically declining use therefore has not been rejected. To dispel this possibility, the annual hours of use given by the hour meters placed on the farm tractors in Hunt's survey are regressed on age for the first seven full years of use. Based on the empirical results, we are unable to reject the hypothesis that the coefficient associated with the variable age is significantly different from zero at the 5% probability level, implying a constant level of use over this time period. In addition, $\sum_{i=1}^{m} OR_i$ is regressed on cumulative hours of use over the sample period used by Hughes to estimate equation (16). The coefficient of determination is almost identical to that reported for equation (16), which one would expect based on our failure to observe any relationship between annual hours of use and age. These results, when added to those reported by Hughes, suggest that the assumption that tractors are used more in the early years of their service life and are therefore consumed in a like manner is not true.

[10] Discussions with agricultural extension agents suggest that farm operators quit making repairs on tractors between the ages of twelve to twenty years. The results presented for equation (17) seem reasonable, since the maximum of sixteen years is within this range.

[11] While the machinery management behavior assumed in this study seems to be the most logical, others could be proposed. The effects of alternative repair and maintenance postponement assumptions on the convexity of the capacity depreciation pattern are examined. The only assumption that altered the convexity of

aggregate management behavior, the distribution of ξ_m over the service life of farm tractors takes the following polynomial form:

$$\xi_m = a_1 m^2 + a_2 m^3. \tag{17}$$

Given equation (17), one can set up a system of two simultaneous equations with two unknowns (a_1 and a_2). Solving this system of equations for a_1 and a_2 and substituting the solution values into equation (17),

$$\xi_m = 0.01172\, m^2 - 0.00049\, m^3. \tag{18}$$

Equations (16) and (18) together provide the necessary information to solve for the set of h_t weights in equation (15).

Comparison with Other Patterns

The final capacity depreciation pattern illustrated by figure 1 is that suggested by the solution of equation (15). This capacity depreciation pattern, denoted by *ED*, is concave rather than convex in shape with respect to the origin, falling in between the OHS and SL capacity depreciation patterns. Interestingly, the ED pattern is substantially different from the geometric decay patterns that, like those assumed by the USDA, are convex in shape with respect to the origin.

Table 1 presents a comparison of the real current market and real productive values for the capital stock and capital flows of farm tractors given by equations (1) through (3) and equations (8) through (10), respectively. Clearly, a substantial difference exists in the values for the capital stock as well as for the net investment and replacement capital flows. The USDA estimates imply a lower level of productive capacity for the stock of farm tractors during 1948–74 than that suggested by the ED capacity depreciation pattern. In addition, the majority of the depreciation of farm tractors purchased new during the post-World War II machinery purchase boom of 1948–53 should not have shown up in the accounts until the late 1950s and early 1960s if the ED capacity depreciation pattern given by equation (15) is reflective of actual losses. This suggests, therefore, that the USDA depreciation series likely underestimates the level of net investment and net farm income during most of the 1950s and overestimates these flows of funds during most of the 1960s. Thus, the researcher's selection of capacity depreciation pattern does have a substantial impact on the magnitude of the capital stocks and capital flows employed in empirical analyses.

Implications for Further Research

Initially, several revisions to the present economic accounts for the farm production sector should be considered in light of the results presented in this study. At a minimum, the real productive value of the capital stock and capital flows for farm tractors suggested by this study should be considered for publication along with their current market value in *Balance Sheet for the Farming Sector* and in *Farm Income Statistics*, respectively. Similar microdata set analyses should also be undertaken to measure the real productive value for other types of farm production machinery and farm buildings. When summed together, analysts and policy makers will be in a better position to assess the level of current expansion of farm business capacity implied by the current dollar estimates of net investment in plant and equipment published in *Farm Income Statistics* and net capital formation proposed by Simunek. When expressed in constant dollars, the capital flow account proposed by Simunek will understate annual real net capital formation and overstate real capital gains to the extent that the present depreciation series in constant dollars overstates capacity depreciation.

The present depreciation series also poses a paradox to the followers of the net farm income estimate published in *Farm Income Statistics*. Its description suggests an accounting of capacity depreciation or that expenditure required to keep capital intact, while the depreciation pattern used to approximate this data series better conforms to that suggested by economic depreciation. To the extent that the current dollar estimate of depreciation overstates the replacement cost for plant and equipment used up during the year, the net farm income data series will be understated. Finally, a study should be undertaken to identify those factors that explain why the current market price for used tractors in secondary machinery markets differs from the average

the ED pattern is one of total postponement of repairs and maintenance in the early stages, constantly decreasing postponement thereafter until all needed repairs and maintenance are made at the end of the service life of the tractor. It seems illogical, if not impossible, to assume that farm operators in general allow their tractors to deteriorate when at their greatest productive level and then make all repairs and maintenance as they approach the end of their service life.

[a] GD-USDA is based upon the geometric decay pattern assumed by the USDA. ED denotes the engineering data pattern given by equation (15). Capital stock at the end of the year.

productive value of tractors of like vintage retained on farms.

There are also important implications for further research associated with estimation of aggregate production functions or investment behavior models. Several previous studies have used the USDA depreciation data series when estimating the parameters in aggregate farm production functions based on factor or relative market shares. Tyner and Tweeten, for example, used the sum of depreciation in current dollars and the opportunity interest charge as a measure of machinery capital services in estimating factor shares for production inputs. Rosine and Helmberger added depreciation to net imputed returns, both expressed in 1957 prices, in estimating the relative market shares for capital inputs. If farm production machinery does wear out at a slower rate in the early years of their service life than in the latter stages as shown for farm tractors, and if the annual rate of embodied technical progress is positive, present measures of annual capital services will lead to inconsistent estimates of production elasticities. In addition, the compound geometric lag hypothesis described by Kmenta would suggest that net investment in farm tractors is a function, in part, of the productive capacity of existing capital and the lagged dependent variable. Thus, the time-series values for the dependent variable and at least two independent variables in a net investment regression model for farm tractors would be directly affected by the capacity depreciation pattern assumed by the researcher. Cromarty, in one of three previous econometric studies focusing on the demand for farm tractors, implicitly assumed the OHS pattern, while Heady and Tweeten assumed a geometric decay pattern. Finally, Griliches examined the effects of both the OHS and geometric decay patterns, concluding that "the truth may lie somewhere in between these two extremes" (p. 202). We suggest that the parameter estimates presented in these studies are also inconsistent due to the

measurement error associated with their dependent and selected independent variables. Further research is needed to determine the relative effect of the ED pattern on these parameter estimates.

Summary

The approach taken to measure the capacity depreciation of farm tractors was one based on utilizing available engineering data. Rather than assuming that the productive capacity of farm tractors declines geometrically, not at all until the last year of its service life, or something in between, information from a recent agricultural engineering survey was used in an attempt to measure actual capacity depreciation. This pattern yields estimates of the real productive value of the existing stock of farm tractors and selected capital flows that differ substantially from those approximated by the USDA. While any specific implications drawn from these results are necessarily limited to those stocks and flows pertaining to farm tractors, there are obvious spill-over effects for other types of farm production machinery and farm buildings. It makes little sense to assume, for example, that farm buildings deteriorate in a geometric fashion. Yet, the estimate of annual depreciation of farm service buildings and farm household dwellings published in *Farm Income Statistics* is also approximated by a constant percentage of the existing capital stock.

As Klein suggests, "Econometricians would be well advised not to lock themselves into committed positions and let data and engineering considerations do some work for them in finding good specifications" (p. 45). The payoffs from working more closely with agricultural engineers in the further development of the economic accounts and model design are likely to be substantial.

Determinants of Milk Advertising Effectiveness

Stanley R. Thompson and Doyle A. Eiler

An analysis of the net returns to dairy farmers from generic fluid milk advertising is made in terms of the ability of advertising to increase the blend price of milk in excess of the cost of advertising. The evaluation of the economic effectiveness of generic fluid milk advertising programs extends beyond the measurement of the direct sales response to advertising. Specifically, the class I-class II price differential and the class I utilization rate are found to be extremely important factors influencing the effectiveness of generic milk advertising programs, while the impact of the price elasticity of supply is relatively minor.

Key words: advertising, fluid milk, generic promotion, milk marketing, polynomial distributed lag.

Most empirical investigations of the economic impact of fluid milk promotion programs have been confined to estimating the responsiveness of sales to given levels of promotion (Clement, Henderson, and Eley; Thompson and Eiler). However, evaluation of the economic effectiveness of a fluid milk advertising program extends beyond the measurement of the direct sales response to advertising.

The major question confronting dairy farmers is whether or not advertising can increase the blend price sufficiently to cover the cost of the advertising effort. This increase in the blend price due to advertising provides a measure of the economic effectiveness of generic fluid milk advertising. Accordingly, the impact of a given advertising expenditure is largely determined by such factors as the class I-class II price differential, the class I utilization rate, the price elasticity of supply, the direct responsiveness of milk sales to advertising and, of course, the level of advertising expenditure. Thus, the purpose of this study is to investigate the economic impact of supply response, class price differentials, and utilization rates on generic fluid milk advertising effectiveness. In this quest, a generalized theoretical framework characterizing milk blend price determination is developed with emphasis placed on the role of generic advertising in changing the blend price.

Economic Model

The industry farm level supply and demand relations are defined, respectively, as

$$Q = S(P), \tag{1}$$

which is equal to the horizontal summation of the marginal cost functions of each firm in the industry, exclusive of the cost of advertising,[1] and

$$Q = D(P,A), \tag{2}$$

where Q is total quantity of milk, P is farm-level price (blend price) for milk, and A is total dollar investment in generic advertising. If the supply and demand relationships are restricted to certain functional forms, the system can be explicitly solved for the equilibrium price (P^*) and, by substitution, for the equilibrium quantity (Q^*).[2]

Stanley R. Thompson is an assistant professor of agricultural economics at Michigan State University, and Doyle A. Eiler is an assistant professor of marketing at Cornell University.

Michigan Agricultural Experiment Station Journal Article Number 7883. Funds supporting this research were provided from the New York State Dairy Promotion Order. The authors wish to acknowledge the helpful suggestions and criticisms of Kenneth L. Robinson and Glynn McBride.

[1] One way to account for advertising investment cost in the analysis is to specify advertising explicitly in the supply function. In this manner, the supply schedule will shift upward by the amount of the advertising investment. However, this procedure complicates the determination of equilibrium values. Alternatively, a more convenient approach is to deduct the cost of advertising directly from the net change in the equilibrium blend price due to advertising. The latter procedure is adopted for this analysis.

[2] Within a static equilibrium framework, Nerlove and Waugh

In most milk markets, a classified pricing system is used to determine the farm-level price of milk. The price farmers receive is a weighted average (i.e., blend price) of exogenously determined prices for fluid milk (class I) and manufacturing milk (class II). This farm level blend price relationship is expressed as follows:

$$(3) \qquad P = \left[\frac{Q_I}{Q}\right] P_I + \left[\frac{Q - Q_I}{Q}\right] P_{II}$$

for $0 < Q_I < Q$, where Q_I is quantity of milk utilized in class I, $Q - Q_I$ is quantity of milk utilized in class II, P_I is price of class I milk, and P_{II} is price of class II milk.[3] Solving equation (3) for Q yields

$$(4) \quad Q = Q_I\,[(P_I - P_{II})/(P - P_{II})] \qquad \text{for } P_{II} < P < P_I.$$

While advertising is not an explicit argument of equation (4), it is implicit in Q_I (see footnote 5 for explicit relationship between Q_I and advertising). Thus, equation (4) can be used in solving for market equilibrium.

If the supply schedule is expressed as a linear function of price,

$$(5) \qquad Q = \gamma + \delta P,$$

then market equilibrium occurs when the quantity supplied in equation (5) equals the quantity utilized in equation (4), or

$$(6) \quad Q_I\,[(P_I - P_{II})/(P - P_{II})] = \gamma + \delta P.$$

Solving equation (6) for the equilibrium blend price (P^*) yields

$$(7) \quad P^* = [-(\gamma - \delta P_{II}) \pm \{(\gamma - \delta P_{II})^2 + 4\delta\,[\gamma P_{II} + Q_I(P_I - P_{II})]\}^{1/2}]/2\delta.$$

The equilibrium blend price (P^*) must lie in the range $P_{II} \leq P^* \leq P_I$. Thus, only the positive root of the quadratic in equation (7) need be considered.

It is evident from this derivation that the equilibrium blend price P^* is influenced by (*a*) the price elasticity of supply, (*b*) the class I-class II price differential, (*c*) the ability of advertising to increase class I sales, and (*d*) the proportion of the total milk production sold as class I.

Figure 1 depicts the comparative static equilibrium effects of fluid milk advertising as defined by equations (4) and (5). Let the initial equilibrium blend price and quantity be P^*_0 and Q^*_0, respectively, and the class I and class II prices (P_I and P_{II}) set the respective upper and lower boundaries of the price-quantity schedule. The prices P_I and P_{II} are exogenously determined under most classified milk-pricing programs (i.e., they are based on a relationship to the Minnesota-Wisconsin price for manufactured products). Further, Q_I^0 is defined as the quantity of class I fluid milk sold to processors at price P_I, and the difference between the total market sales Q^*_0 and Q_I^0 is the quantity sold as class II. Suppose that fluid milk advertising increases the quantity of class I sales from Q_I^0 to Q'_I and that the effect of this increase in class I sales is to shift the price-quantity relationship from $D_0D'_0$ to $D_1D'_1$. Allowing for supply response, the effect of the increased class I sales is not to increase the blend price to P'_0 at quantity Q^*_0 but rather, after complete adjustment, to establish a new *ex post* equilibrium at a somewhat lower price P^*_1 with a somewhat greater total quantity Q^*_1.

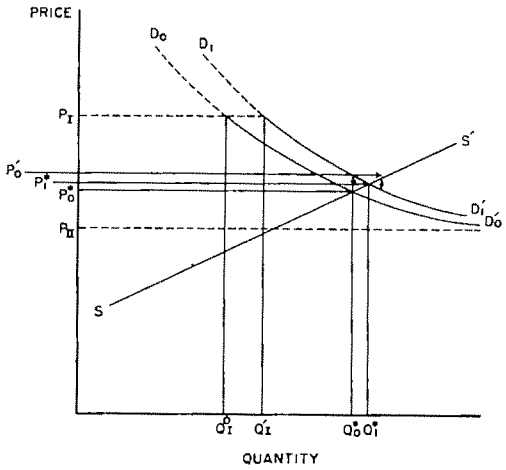

Figure 1. Blend price—quantity relationships and equilibrium prices resulting from a shift in demand

Empirical Results

The Data and the Model

Data were obtained on fluid milk sales and prices, personal income, population, competitive beverage prices, generic milk advertising expenditures, and other competitive beverage

have conceptualized the unique nature of advertising without supply control. For the most part, Nerlove and Waugh's theoretical conceptualization fits the conditions surrounding the fluid milk advertising problem and, therefore, a special case of their framework is adopted here.

[3] When $Q_I = 0$, $P = P_{II}$, and when $Q_I = Q$, $P = P_I$.

advertising in the New York City standard metropolitan statistical area (SMSA). Monthly observations were available from January 1971 to March 1974 (Thompson, Eiler, and Forker). Considerable monthly variations in both sales and advertising expenditures prevailed over the thirty-nine-month period.

Class I milk sales include sales of regular whole milk, low fat milk, skim milk, and milk drinks. These sales data represent actual net fluid milk sales after adjusting for shipments entering and exiting the SMSA. Moreover, since sales differ dramatically depending on the day of the week, each monthly sales statistic was adjusted for the number of each day of the week in the month and placed on a daily basis. These monthly adjusted sales data were placed on a per capita basis using the population within the SMSA.

The generic fluid milk advertising data are defined according to the media coverage area (MCA), where the population of the New York City MCA is about 50% larger than its respective SMSA population. The monthly advertising expenditures were placed on a per capita basis according to the MCA population and then deflated by an index of the cost of prime-time spot television. More than 85% of the media expenditures were for television, and no basic changes occurred in the advertising theme during the sample period.

Since class I sales are substantially less than total milk sales and fluid milk advertising is presumed to directly influence only class I sales, a single equation econometric model can be estimated. In addition, since much of the empirical advertising literature suggests the existence of diminishing marginal returns to advertising (see Simon), an econometric sales response model capable of exhibiting this characteristic was specified. Using a polynomial distributed lag model to obtain an estimate of the long-run influence of advertising on sales, the following ordinary least-squares estimates were obtained:[4]

$$
\begin{aligned}
(8)\quad \ln q_I = {} & 0.8839 + \underset{(1.02)}{0.0082}DJAN \\
& + \underset{(4.11)}{0.0314}DFEB + \underset{(3.45)}{0.0267}DMAR \\
& + \underset{(1.65)}{0.0139}DAPR + \underset{(0.44)}{0.0036}DMAY \\
& - \underset{(1.67)}{0.0136}DJUN - \underset{(14.36)}{0.1037}DJUL \\
& - \underset{(12.04)}{0.0908}DAUG - \underset{(2.74)}{0.0202}DSEP \\
& + \underset{(0.36)}{0.0026}DOCT - \underset{(1.37)}{0.0096}DNOV \\

& + \underset{(5.20)}{0.0044}\ln a_{t-4} + \underset{(3.99)}{0.0035}\ln a_{t-5}; \\
& \bar{R}^2 = 0.966; \qquad DW = 1.98;
\end{aligned}
$$

where q_I is per capita daily class I milk sales in ounces, adjusted for the type of days in the month, i.e., number of Sundays, Mondays, etc.; *DJAN . . . DNOV* are eleven zero-one dummy variables with December as the base class; *INC* is deflated per capita annual personal income in dollars; *PRC* is deflated (by consumer price index, 1967 = 100) retail price in dollars of whole fluid milk in paper half gallons; and the a_{t-i} are deflated actual per capita monthly media advertising expenditures (in dollars) lagged i periods, where $a = A/\text{SMSA}$ population. The figures in parentheses are computed t-ratios of the estimates. The combined direct and carryover elasticity of advertising is 0.0212 (a t-ratio of 4.84).

Since the theoretical model previously presented focused on market equilibrium and the relationship between class I sales and fluid milk advertising (equation (8)) was estimated on a per capita basis to obtain an empirical estimate of the market level blend price-quantity relationship, an aggregation procedure is necessary. Using the mean value for all of the variables except advertising, the per capita demand function, equation (8), can be aggregated to yield the following class I market demand function:[5]

[4] Using the Lagrangian interpolation procedure, a polynomial distributed lag model was used to estimate the long-run influence of advertising. The criteria and procedures used to select the degree of polynomial and length of the lag can be found in Thompson, Eiler, and Forker. Based on these criteria, a third-degree polynomial of lag length five was selected to best represent the lagged response of sales to advertising in New York City.

[5] The market demand function (equation (9)) is derived by using the estimated per capita class I demand function (equation (8)) and the assumptions: (*a*) the average SMSA population in New York City is 11,702,221, (*b*) 14.88372 fluid ounces per pound of 3.5% test milk, (*c*) 365 days per year, (*d*) 100 pounds per hundredweight, and (*e*) 2.290765 is the sum of the nonadvertising coefficients

(9) $$Q_I = 2{,}869{,}787e^{2.2908}a^{0.0212}.$$

Employing the analytical framework and the estimated sales response model, the equilibrium blend price associated with a particular advertising level can be calculated. The difference between the equilibrium blend price with a particular advertising level and the equilibrium blend price with no advertising is the imputed return dairy farmers receive from the advertising program, i.e., the increase in the blend price due to advertising.[6] However, as indicated by the economic model, the class price differential, the utilization rate, and the nature of supply response all have a direct bearing on the returns dairy farmers receive. In the subsequent discussion the role of each of these factors in determining the blend price increase associated with advertising is examined further.

Price Differentials and Utilization Rates

The Federal Milk Marketing Order No. 2 for the New York-New Jersey milk marketing area specifies that the price for class I milk is the Minnesota-Wisconsin price in the second preceding month plus \$2.40 per hundredweight (USDA 1971), whereas the class II price is the current month's Minnesota-Wisconsin price plus seasonal adjustment. Thus, the actual class I-class II price differential may be greater or less than \$2.40 per hundredweight, depending upon the month-to-month Minnesota-Wisconsin price variation and the seasonal adjustment (USDA 1971). Since substantial variation in the class price differential can occur, the size of this differential is potentially an important determinant of the effectiveness of generic advertising.[7]

Using a price elasticity of supply of 0.8 (Jackson, p. 67), the sensitivity of the blend price increase due to a deflated monthly advertising expenditure of \$0.00575 at selected class price differentials and utilization rates is shown in table 1.[8] As shown, the change in the blend price due to advertising is quite sensitive to both changes in the class I-class II price differential and the utilization rate. The estimated sales response to advertising (from equation (9)) is identical for each cell in table 1; only the economic effectiveness differs.

While different milk marketing areas generally experience different class I utilization rates, within a particular milk market these

evaluated at the mean value of their variables. Therefore, $Q_I = \frac{(11{,}702{,}221)(365)}{14.88372(100)} e^{2.290785}a^{0.02115737} = 2{,}869{,}787e^{2.290785}a^{0.02115737}$.

[6] Since the double-log sales response function is incapable of handling zero advertising expenditures, a "very small" monthly per capita advertising level of \$0.0001 was used.

[7] For example, during 1975 the corresponding range in the monthly class I-class II price differentials for the following federal order markets were: New York City, \$1.58–\$2.60 per hundredweight; Chicago, \$0.24–\$1.15 per hundredweight; New Orleans, \$1.83–\$2.74 per hundredweight; and Oklahoma Metro, \$0.96–\$1.87 per hundredweight (USDA 1975–76).

[8] This represents the "optimum" level of advertising for New York City in the sense that with a supply elasticity of 0.80 net producer returns to advertising are maximized (Thompson, Eiler, and Forker, p. 13). The blend price increases reported in table 1 depend upon the level of advertising. Increasing the level of advertising would increase the blend price, but it would also cause the ridge line in table 1 to migrate toward the southwest due to the diminishing returns of advertising. Regardless of the level of advertising, the relationship between adjacent table elements remains the same.

Table 1. Increase in the Equilibrium Blend Price Due to Advertising, New York City SMSA

Utilization Rate in Class I	Class I-Class II Price Differentials							
	3.20	2.80	2.40	2.00	1.80	1.60	1.40	1.20
	\$/cwt.

0.75	0.167	0.149	0.130	0.110	0.100	0.091	0.080	0.069
0.80	0.177	0.158	0.137	0.117	0.106	0.096	0.084	0.074
0.85	0.186	0.166	0.145	0.123	0.113	0.101	0.089	0.078
0.90	0.197	0.175	0.153	0.130	0.118	0.106	0.094	0.082
0.95	0.206	0.184	0.160	0.136	0.124	0.111	0.099	0.086

Note: The figures in this table are based on deflated per capita monthly direct media advertising expenditure of \$0.00575 and price elasticity of supply of 0.80.

[a] The increase in blend price is less than the cost of the advertising program.

utilization rates are quite stable over time and indeed substantially less volatile than the class I-class II price differential. Thus, an awareness of the magnitude of this price differential and its expected change over time has some important advertising program planning and policy implications.

As evident from table 1, the higher the class I utilization rate, the greater the impact of advertising on the blend price. Also, since a successful milk advertising program has the effect of shifting milk from class II to class I utilization, the greater the class I-class II price differential, the greater the increase in the blend price (where $P_I > P_{II}$). Assuming a 50% utilization rate, the increase in the blend price due to advertising is 16% less for a class I-class II price differential of $2.00 per hundredweight than for a price differential of $2.40 per hundredweight.

A major implication from the relationships shown in table 1 is that the benefits from advertising are greatest in milk markets with high class I-class II price differentials and high class I utilization rates. These specific findings are, of course, conditional on the highly significant sales response to advertising relationship observed in New York City. Nonetheless, the general relationships between adjacent elements in table 1 hold regardless of the magnitude and/or significance of the estimated advertising parameter.

Clearly, the degree of responsiveness of sales to advertising is not the only factor affecting the economic effectiveness of fluid milk utilization rates, and class price differentials are highly important determinants. In particular, the response of sales to advertising in other markets may be substantially less than the estimated response in New York City, but the advertising effort can still be profitable if the class price differentials and the utilization rates are high.

Supply Response and Advertising

The change in the blend price from advertising at various price elasticities of supply is shown in figure 2. An inverse relationship between the price elasticity of supply and the blend price increase is observed. The sensitivity of changes in the blend price to alternative elasticities of supply, however, is relatively low—especially over realistically small changes in elasticities. For example, increases in the supply elasticity from the short-run level of

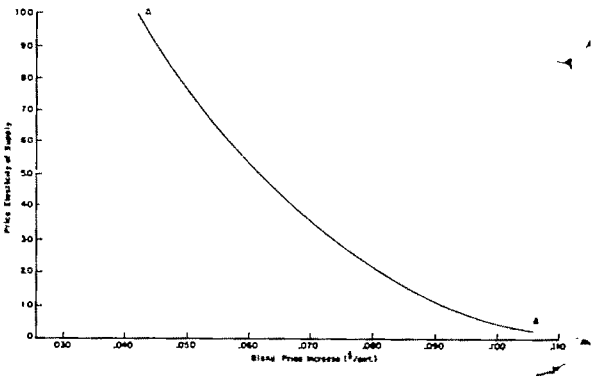

Figure 2. Blend price increase due to advertising for alternative supply elasticities, New York City SMSA. Based on: (*a*) deflated per capita monthly direct media advertising expenditure of $0.00575, (*b*) class I-class II price differential of $2.40 per hundredweight, and (*c*) class I utilization of 53%.

0.25 in the northeast United States to the long-run level of 0.80 (Jackson) decrease the change in the blend price from $0.1025 to $0.095, or by only about 7%.

There are an infinite number of figures like figure 2 for various combinations of class price differentials and utilization rates. Also, figure 2 and table 1 are related; that is, where the class I-class II price differential equals $2.40 per hundredweight, the utilization rate equals 53%, and the supply elasticity equals 0.80, the change in the blend price common to both figure 2 and table 1 is approximately $0.096 per hundredweight.[9]

Net Producer Returns

Since the estimated effect of advertising on sales in equation (8) is positive, the change in the equilibrium blend price (equation (7)) is also positive. However, the important question confronting dairymen and those managing the advertising program is whether or not the increase in the blend price is greater than the cost of the advertising effort.

The deflated per capita monthly direct media advertising expenditure of $0.00575 implies a cost of $0.045 per hundredweight to finance the program.[10] Thus, the areas where

[9] During the sample period of this study, the observed class I milk utilization rate in Federal Order No. 2 averaged 53%.

[10] Direct media cost = $0.00575 × 12 × (mean New York City SMSA population) × (current cost of media index) = $0.00575 × 12 × 11,702,221 × 1.80 = $1,453,416. Total cost of the advertising program includes the direct media cost plus the cost of program development and administration. In New York, these costs are

the increase in the blend price exceeds the cost of the advertising program are located southwest of the ridge line drawn in table 1. Notwithstanding the precise position of this ridge line, the higher the class I utilization and the greater the class I-class II price differential, the greater the returns to advertising.[11]

In Federal Order No. 2, where the class I utilization rate has averaged 50% to 55% and the class I-class II price differential about $2.40 per hundredweight, the net increase in the blend price over program costs ranges from $0.046 to $0.053 per hundredweight for utilization rates of 50% and 55%, respectively. The reader should bear in mind that these specific returns are conditional on the responsiveness of sales to advertising in the New York City market, the selected level of advertising expenditure, and the assumed price elasticity of supply.[12]

Summary and Implications

The general findings are that both the class I-class II price differential and the class I utilization rate are extremely important factors influencing the effectiveness of generic milk advertising programs. On the other hand, the impact of the price elasticity of supply on the economic effectiveness of advertising was relatively minor. Although our empirical investigation was for a particular market, the basic relationships hold regardless of the responsiveness of fluid milk sales to advertising and are extendable to markets for which advertising response estimates are not available.

A major implication of this study is that generic fluid milk advertising is likely to be more effective in markets maintaining "large" class I-class II price differentials, "high" class I utilization rates, and "low" price elasticities of supply. Since these factors are generally determined by the structural characteristics of milk markets, their interrelationships have important regional implications for improved generic advertising decision making. Further, the class I-class II price differential in many milk markets varies substantially over time. Thus, improved temporal expenditure decisions can be made. The advertising program planning implications of this temporal variability can be particularly important, since the level of the class I-class II price differential can often be anticipated several months in advance.

approximately 46% of direct media cost. Thus, the total cost of the advertising program would be $2,121,987. On a hundredweight basis the cost is $0.045 per hundredweight. The above calculations assume a perfect congruence between the media coverage area, SMSA, and the milk shed. As divergences occur (as they always do in the real world), leakages appear that increase the cost of executing the program relative to the benefits that accrue to the program's supporters. New York dairy farmers have this problem in the New York media coverage area, where 20% of the milk sold does not contribute to the advertising program.

[11] The greater the responsiveness of sales to advertising, the more successful advertising will be in increasing the blend price. However, in markets where sales are less responsive than those estimated for the New York City market, the ridge line will move toward the southwest corner of table 1, notwithstanding identical levels of advertising.

[12] These results assume a price elasticity of supply of 0.80 and the estimated sales response function in equation (8).

On Two Strategies for Choosing Principal Components in Regression Analysis

Ron C. Mittelhammer and John L. Baritelle

Two traditional methods used to form principal components (PC) regression estimates are reviewed, and small sample properties of the estimates are compared with OLS estimates. A Monte Carlo experiment is used to facilitate comparisons. Theoretical considerations and empirical observation indicate that the PC techniques tend to produce estimates lower in mean square error (MSE) than OLS estimates under conditions of high multicollinearity, low R^2, and small sample size. Although under these conditions the PC techniques may be preferred to OLS in the relative MSE sense, MSE in the absolute sense may still render the PC estimates useless in applications.

Key words: mean squared error, multicollinearity, principal components, regression.

The use of principal components (PC) in regression analysis has infrequently appeared in the literature since Hotelling first proposed the technique in 1933. Recently, an illuminating article by McCallum demonstrated the potential usefulness of PC in regression analysis (PC-OLS) when multicollinearity is present. Cheng and Iglarsh also discuss the use of PC-OLS in cases of strong multicollinearity. Conspicuously missing from the literature is a comparison of the two traditional methods of determining the components used to form PC-OLS estimates.

One method deletes those components having small characteristic roots. Deletion based on small characteristic roots implies little loss in the total variation of the independent variables. Kendall discusses this method, while it is applied by others such as Pidot and Barrett, Gerardi, and Hart. Kendall mentions deletion of components based upon t-ratios, and Massy uses such a criterion.

This paper briefly reviews the process of principal component deletion in regression analysis and develops a theory of component deletion via the characteristic root (CRC) and t-value (TVC) criteria (for a thorough treatment of principal components, see Anderson). The meaning and some of the statistical properties of the derived coefficients under each criterion are examined. To facilitate comparisons, a simulation model using each criterion is employed.

Ron C. Mittelhammer is a research economist, stationed at Washington State University, and John L. Baritelle is a research economist with the Commodity Economics Division, Economic Research Service, U.S. Department of Agriculture.

The authors wish to thank Leroy Blakeslee, Millard Hastay, Max R. Langham, David Price, Min-Chiang Wang, and an anonymous reviewer for their helpful suggestions.

Principal Component Regression Model

Assume the classical linear model

$$Y = X\beta + U, \tag{1}$$

where β is a $k \times 1$ vector of unknown population parameters to be estimated associated with the fixed set of independent variables contained in the $(n \times k)$ X matrix, and the $(n \times 1)$ U vector contains random disturbances distributed $N(0, \sigma^2 I_n)$. Both X and Y are expressed in deviations from the mean, and the X's are divided by their respective standard deviations.

Let W be the $k \times k$ matrix consisting of $k \times 1$ orthonormal characteristic vectors (w_i) of the correlation matrix $T^{-1}(X'X)$, where $T = n - 1$. The $n \times k$ matrix of principal components (Z) stands in the following relation to X:

$$Z = XW \text{ and } ZW' = X, \tag{2}$$

since by orthogonality $W^{-1} = W'$.

Substituting equation (2) into equation (1)

for X, the relationship between Y and the principal components is defined as

$$Y = ZW'\beta + U = Z\beta^c + U, \tag{3}$$

where $\beta^c = W'\beta$ is the $k \times 1$ vector of population parameters corresponding to the principal components Z. The OLS estimate of β^c can be written as

$$\begin{aligned} b^c &= (Z'Z)^{-1}Z'Y \\ &= (W'X'XW)^{-1}W'X'Y \\ &= W'(X'X)^{-1}WW'X'Y \\ &= W'(X'X)^{-1}X'Y = W'b. \end{aligned} \tag{4}$$

Hence, the OLS estimates of the original parameters in equation (1) can be formed as

$$b = Wb^c. \tag{5}$$

A principal component OLS (PC-OLS) estimate of the β vector in equation (1) is an estimate that is formed by deleting the effects of certain components in estimating b by equation (5). This can be represented by replacing certain column vectors of W with zero vectors, resulting in a new matrix W^*. The PC-OLS estimate for a given sample can be represented as[1]

$$b^* = W^*b^c. \tag{6}$$

The PC-OLS estimate of equation (1) is therefore defined as

$$Y = Xb^* + e^*. \tag{7}$$

Different estimators within the PC-OLS class can be defined depending on the criterion used to delete components.

Characteristic Root Criterion

This criterion eliminates components having small characteristic roots. The motivation for utilizing such a criterion may be given in two parts.

First, components having small characteristic roots account for only a small part of the variation in the X variables. This can be seen by first noting that the total system variation (TSV) in the X variables can be represented as

$$\begin{aligned} \mathrm{TSV}(X) &= \mathrm{tr}(X'X) = \mathrm{tr}(X'XWW') \\ &= \mathrm{tr}(W'X'XW) = T\,\mathrm{tr}\,\Lambda \\ &= T\sum_{i=1}^{k}\lambda_i, \end{aligned} \tag{8}$$

since the matrix of characteristic vectors W can be used to diagonalize $T^{-1}X'X$. The TSV in the components Z is equal to TSV(X), since $W'X'XW = Z'Z$. Therefore, the proportion of the total system variation in the data set that is accounted for by the ith component is given by

$$\mathrm{V}(Z_i)/\mathrm{TSV}(Z) = T\lambda_i/T\sum_j\lambda_j = \lambda_i/\sum_j\lambda_j. \tag{9}$$

The smaller is the characteristic root λ_i, the smaller is the proportion of the total system variation accounted for by component Z_i.

Second, discarding components with small characteristic roots may result in large reductions in the variances of the estimates b^*_i. Since b^* is a linear combination of variables distributed $N(\beta^c, \Sigma_{b^c})$, b^* is distributed $N(W^*\beta^c, W^*\Sigma_{b^c}W^{*\prime})$. If

$$\Sigma_{b^c} = \sigma^2(Z'Z)^{-1} = \sigma^2(T\Lambda)^{-1}, \tag{10}$$

then

$$\Sigma_{b^*} = W^*\Sigma_{b^c}W^{*\prime} = \sigma^2T^{-1}W^*\Lambda^{-1}W^{*\prime}. \tag{11}$$

When no components are deleted, the ith diagonal entry of equation (11) represents an orthogonal decomposition of the variance of b_i as

$$\mathrm{var}\ b_i = \sigma^2T^{-1}\sum_{j=1}^{k}\frac{w_{ij}^2}{\lambda_j}. \tag{12}$$

Assuming that the last $k - k^*$ components are deleted, the gain in precision when using b^*_i in place of b_i can be written as

$$\mathrm{var}\ b_i - \mathrm{var}\ b^*_i = \sigma^2T^{-1}\sum_{j=k^*+1}^{k}\frac{w_{ij}^2}{\lambda_j}. \tag{13}$$

Deleting components with small characteristic roots is equivalent to deleting the variance terms having the smallest denominators in the decomposition of equation (12). This can lead to a great reduction in the variance of the estimator of β_i if the w_{ij}'s are relatively large and the λ_j's are relatively small. However, the magnitudes of the w_{ij}'s are determined by a complex relationship among the entries of the correlation matrix $T^{-1}(X'X)$, and little can be inferred about a given w_{ij} on the basis of the magnitude of a characteristic root.

Given the orthonormality of the set of vectors $\{w_1, w_2, \ldots, w_k\}$, the w_{ij}'s are bounded by $0 \le w_{ij}^2 \le 1$ and $\sum_j w_{ij}^2 = \sum_i w_{ij}^2 = 1$. Therefore, the variances of the estimates of one or more

[1] Variables in the original X-frame of reference are not deleted, and an estimate of the full β vector is always available.

entries in β are reduced relative to OLS estimation. Unfortunately, when using CRC there is no control on the bias introduced, where

$$(14)\quad \text{bias } b^*_i = Eb^*_i - \beta_i = \sum_{j=1}^{k^*} w_{ij}\beta_j^c - \sum_{j=1}^{k} w_{ij}\beta_j^c = -\sum_{j=k^*+1}^{k} w_{ij}\beta_j^c.$$

The principal components are functions of the correlation matrix $T^{-1}(X'X)$ without regard to the dependent variable Y, while the estimates of β_j^c are functions of the dependent variable in addition. Thus, the CRC results in deletion decisions made without information regarding the correlation between the dependent variable and the components. Referring to the mean square errors of the estimates, this deletion criterion can cause difficulties of varying degree, depending on the problem. The mean square error of b^*_i is defined as

$$(15)\quad \text{MSE } b^*_i = \text{var } b^*_i + (\text{bias } b^*_i)^2 = \sigma^2 T^{-1}\sum_{j=1}^{k^*}\frac{w_{ij}^2}{\lambda_j} + \left(-\sum_{j=k^*+1}^{k} w_{ij}\beta_j^c\right)^2.$$

The mean square error of the OLS estimate b_i is simply its variance in equation (12), since b_i is an unbiased estimate. Therefore, the mean square error of the PC-OLS estimate relative to the OLS estimate can be written as

$$(16)\quad \frac{\text{MSE } b^*_i}{\text{MSE } b_i} = \frac{\sum_{j=1}^{k^*} w_{ij}^2/\lambda_j}{\sum_{j=1}^{k} w_{ij}^2/\lambda_j} + \frac{\left(-\sum_{j=k^*+1}^{k} w_{ij}\beta_j^c\right)^2}{\sigma^2 T^{-1}\sum_{j=1}^{k} w_{ij}^2/\lambda_j}.$$

Equation (16) is seen to be the sum of the variance of b^*_i relative to the variance of b_i and of the (bias b^*_i)^2 relative to the variance of b_i.

Given a population relation as in equation (1), the effect of the bias on the relative mean square error of b^*_i to b_i is less, the smaller the sample size (smaller T) and the smaller the R^2 (the greater the σ^2).[2] In addition, highly multicollinear data result in one or more components having very small characteristic roots. Due to the bounds on the w_{ij}, one or more estimates b^*_i of β_i may have greatly reduced variances relative to OLS estimates.

The variance of b_i can be written in the following illustrative form (see Theil, p. 166):

$$(17)\quad \text{var } b_i = \sigma^2[(1 - R_i^2)X'_iX_i]^{-1},$$

where R_i^2 is the coefficient of determination corresponding to the linear regression of X_i on the remaining explanatory variables. As the linear relation (multicollinearity) between X_i and the remaining variables becomes more severe, R_i^2 approaches one and var b_i increases without bound. In this sense, the effect of the second term in equation (16) may be small.

In general, the CRC is more favorable in situations characterized by small sample size, low R^2, and high multicollinearity. A consistent estimate of the MSE of b^*_i relative to b_i is available by inserting the appropriate OLS estimates of b^c and σ^2 into equation (16).

t-Value Criterion

The inherent lack of control on the bias introduced when deleting components on the basis of the CRC suggests possible advantages in using a deletion criterion that tests the statistical significance of the regression coefficients b^c before deletion. A simultaneous testing procedure of the Bonferroni type based on the t-distribution might be used to test the null hypothesis that $\beta_j^c = 0$ for $j = 1, \ldots, k$.[3] The PC-OLS estimate of the β vector, using the TVC for deletion, is

$$(18)\quad b^* = WI_{(\tau)}b^c,$$

where $I_{(\tau)} = I - [I_{(-\tau_j, \tau_j)}(b_j^c)]$ is a $k \times k$ diagonal matrix, I is the $k \times k$ identity matrix, $\tau_j = t_j(s^2(T\lambda_j)^{-1})^{1/2}$, $j = 1, \ldots, k$, t_j is the critical t-value of the jth hypothesis test, s^2 is the square of the standard error of the equation, $I_{(a,\,b)}(X)$ is the indicator function (Mood, Graybill and Boes, p. 20),[4] and $[I_{(-\tau_j, \tau_j)}(b_j^c)]$ is

[2] The R^2 coefficient is used in the nonstochastic X case as a purely descriptive measure.

[3] The univariate t-test is applied to each component regression coefficient separately. Using the Bonferroni inequality, the simultaneous confidence coefficient applicable to the k univariate tests exhibits the lower bound $1 - \sum_{i=1}^{k}\alpha_{ti}$ where α_i is the probability of type I error for the ith univariate test.

[4] Essentially,

$$I_{(a,\,b)}(X) = \begin{cases} 1 \\ 0 \end{cases} \text{ when } \begin{cases} a < X < b \\ \text{otherwise} \end{cases}.$$

a $k \times k$ diagonal matrix, exhibiting the indicator functions for $j = 1, \ldots, k$ on the diagonal.

Equation (18) indicates that the deletion of components depends upon the τ_j, which are in turn functions of the stochastic variable s^2 and of the chosen critical t-values. Specifically, a column vector of W is transformed to the zero vector whenever its associated regression coefficient b_j^c is judged not significantly different from zero using the t-test. The expected value of the ith entry of b^* is

$$(19)\quad Eb^*_i = \sum_j w_{ij} \int_0^\infty \left(\int_{-\infty}^{-\tau_j} b_j^c f_j(b_j^c)\mathrm{d}b_j^c + \int_{\tau_j}^{\infty} b_j^c f_j(b_j^c)\mathrm{d}b_j^c \right) g(s^2)\mathrm{d}s^2,$$

where

$$f(b^c, s^2) = \left(\prod_{i=1}^{k} f_i(b_i^c) \right) g(s^2);$$

that is, the joint density function of b^c and s^2 is the product of the marginal density functions, since all the b_i^c are distributed independently (being distributed normally, with zero covariances), and the b^c vector is distributed independently of s^2 (see Dhrymes, pp. 149–50).

The bias of b^*_i can be written as

$$(20)\quad \text{bias } b^*_i = Eb^*_i - \beta_i = -\sum_j w_{ij} \int_0^\infty \int_{-\tau_j}^{\tau_j} b_j^c f(b_j^c) g(s^2)\mathrm{d}b_j^c\mathrm{d}s^2.$$

Letting $t_j = t$ for all j, as $t \to \infty$, the bias b^*_i approaches $-\sum_j w_{ij}\beta_j^c$, and as $t \to 0$, the bias b^*_i approaches zero.[5]

The covariance matrix of b^* is

$$(21)\quad E(b^* - Eb^*)(b^* - Eb^*)' = E(WI_{(\tau)}b^c - WE(I_{(\tau)}b^c))(WI_{(\tau)}b^c - WE(I_{(\tau)}b^c))' = W[E(I_{(\tau)}b^c b^{c\prime} I_{(\tau)}) - E(I_{(\tau)}b^c)E(b^{c\prime} I_{(\tau)})]W'.$$

A typical diagonal element of equation (21) can be written as

$$(22)\quad \text{var } b^*_i = \sum_j \sum_k w_{ij}w_{ik} \left(\int_0^\infty \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} (1 - I_{(-\tau_j, \tau_j)}(b_j^c))(1 - I_{(-\tau_k, \tau_k)}(b_k^c)) b_j^c b_k^c f(b_j^c) \cdot f(b_k^c) g(s^2)\mathrm{d}b_j^c\mathrm{d}b_k^c\mathrm{d}s^2 - E((1 - I_{(-\tau_j, \tau_j)}(b_j^c))b_j^c)E((1 - I_{(-\tau_k, \tau_k)}(b_k^c))b_k^c) \right).$$

When t is in the neighborhood of zero, the var b^*_i is close to the var b_i, and as t becomes extremely large and increases without bound, var b^*_i approaches zero.[6]

Unfortunately, it is not necessarily true in the case of the TVC that the var $b^*_i \leq$ var b_i. The variance of the component estimator may actually be greater than the variance of the OLS estimator. This possibility is illustrated by a Monte-Carlo experiment presented in the next section, which includes cases where var $b^*_i >$ var b_i for some i.[7]

The relative MSE of the TVC estimator compared with the OLS estimator can be written in a general way as

$$(23)\quad \frac{\text{MSE } b^*_i}{\text{MSE } b_i} = \frac{\text{var } b^*_i}{\text{var } b_i} + \frac{(\text{bias } b^*_i)^2}{\text{var } b_i},$$

where the var b^*_i and bias b^*_i are given by equations (22) and (20), respectively. The TVC does not lend itself to a general discussion of the behavior of the estimates under varying sample sizes, degree of multicollinearity, or level of R^2 primarily because the expressions for the variances of b^*_i are extremely complicated.

Nonetheless, a few general comments can be made concerning the use of the TVC in forming PC-OLS estimates. First, the control on the bias b^*_i becomes relatively less important the higher the degree of multicollinearity, given that X_i is involved in the multicollinearity problem in a general way (recall equation (17)). Second, it is discomforting to know that the relative variance ratio in equation (23) may be greater than one, indicating that TVC-derived PC-OLS estimates would not only be biased but would have greater variance than the OLS estimates. Lastly, it is not clear what critical value of t should be used, nor whether a different critical value of t should be used for each coefficient test.

A Monte-Carlo Experiment

A Monte-Carlo experiment was conducted to examine the behavior of the TVC criterion using a conventional t critical value set at the 0.05 level of significance. A lower value of the t critical value is also examined. The CRC

[5] The behavior of the bias b^*_i between the extreme limits for t is not generally monotonic, due to the fact that the individual integrals in equation (20) may converge at differing rates.

[6] The behavior of the variance of b^*_i between the extreme limits for t will not be monotonic, in general, due to the fact that the individual integrals in the sum in equation (22) may converge at different rates.

[7] The authors have tried in vain to construct a general proof of the possibility that var $b^*_i >$ var b_i. The difficulty is that the variance expressions as equation (22) do not have solutions in closed form.

estimator is included in the experiment for comparison purposes. The function to be estimated under the differing criteria is specified as $Y = -42 + 10X_1 + 27X_2 + 36X_3 + 4X_4 + U$. The values of the parameters are arbitrarily selected. The mean values for the X's are selected randomly from the integers 1 to 100 and their variances established at one-fourth of their means. Three sets of zero-order correlation coefficients are selected to represent varying degrees of collinearity. For a given set of correlation coefficients, an X matrix of twenty-five observations is selected. Then, for each X matrix and for an $R^2 = 0.90$, 500 different Y vectors of twenty-five observations each are generated. The procedure is duplicated for $R^2 = 0.50$.

The three X matrices are fixed in repeated sampling. The correlation matrices of X are orthogonalized by the appropriate matrix of characteristic vectors (W). A new set of variables is then formed for each X matrix using $Z = XW$ (recall equation (2)); and for each of the 500 Y vectors, a regression equation is estimated.

The characteristic vectors corresponding to those characteristic roots whose values are less than the value established as the deletion criterion are replaced with zeros. As in equation (6), the b^c are transformed to the original frame of analysis, giving the vector of PC-OLS estimates b^*. This is done for 500 samples with two different characteristic root criteria equal to 1.00 and 0.50.[8]

Similarly, for the same 500 samples, regression coefficients of the principal components are set to zero when the null hypothesis $\beta_j^c = 0$ cannot be rejected. The t-value deletion criteria are first set at $t = 2.0860$, which for twenty degrees of freedom represents a 0.95 confidence interval for each univariate test, for a simultaneous confidence coefficient greater than or equal to 0.80. A t of 1.0000 is also used, implying a simultaneous confidence coefficient greater than or equal to 0.36. The new vector b^{*c} is then transformed back to the original frame of reference: $b^* = WI_{\sigma}b^c$.

For each criterion and for each of the given estimated coefficients, three summary statistics are developed. First, the standardized bias of b^*_i is calculated as $(\bar{b}^*_i - \beta_i)/\sigma_{b_i}$, where $\bar{b}^*_i = \sum_l b^*_{l,i}/500$, the summation is over 500 observations, and σ_{b_i} represents the true OLS standard deviation of the specified population parameter estimate.

The second calculation involves the ratio of the variance of each b^*_i about its empirical mean in relation to the true OLS variance, $\sigma_{b_i}^2$: $\sum_l (b^*_{l,i} - \bar{b}^*_i)^2/499\sigma_{b_i}^2 = s_{b^*_i}^2/\sigma_{b_i}^2$.

Lastly, the empirical mean square error of each b^*_i is compared with the true OLS variance of b_i, that is, $(s_{b^*_i}^2 + (\text{bias } b^*_i)^2)/\sigma_{b_i}^2$. The results generated from the experiment are too numerous to be presented here in full. Hence, the following descriptive statistics are used to facilitate a discussion of the results: average absolute value of the standardized bias (AASB): $AASB = \sum_{i=1}^{k} |\text{standardized bias}_i|/k$; average relative variance (ARV): $ARV = \sum_{i=1}^{k} (\text{var } b^*_i/\text{var } b_{i,\,OLS})/k$; average relative mean square error (ARMSE): $ARMSE = \sum_{i=1}^{k} (\text{MSE } b^*_i/\text{var } b_{i,\,OLS})/k$.

Results of the Monte-Carlo Experiment

The two criteria of component deletion, CRC and TVC, behave quite differently and distinctly under different levels of multicollinearity (table 1). As discussed in the section on the characteristic root criterion, the CRC does not take the bias into account when deleting components. The TVC, on the other hand, does account for bias in the sense of testing the significance of component coefficients before a decision concerning deletion is made. The results in table 1 exhibit the consequences vividly, where the CRC produce in the aggregate sense more biased estimates than estimates using the TVC.[9] This result was typical for the estimates of the individual β_i (which are not all presented here).

[8] A characteristic root of $\lambda = 1$ can be thought of as the average value of a characteristic root when a correlation matrix is factorized: $\text{tr}\Omega = T^{-1}\text{tr}(X'X) = T^{-1}\text{tr}(X'XWW') = T^{-1}\text{tr}(W'X'XW) = T^{-1}\text{tr}(Z'Z) = \text{tr}\Lambda = \sum_{i=1}^{k} \lambda_i$, and since $\text{tr}\Omega = k$, the average characteristic root is $1 = \sum_{i=1}^{k} \lambda_i/k$. Then, using this CRC, a component is deleted if it has a below-average characteristic root. Further discussion of the $\lambda = 1$ deletion criterion can be found in Rummel, pp. 357–65.

[9] The results in the highly multicollinear case are identical for $\lambda = 1$ and $\lambda = 0.5$, since one component accounts for 91.80% of the variation and has a characteristic root equal to 3.67. Clearly, the other three characteristic roots are all less than 0.5, and so the same number of components are deleted under each criterion.

Table 1. Summary of Results from Monte-Carlo Study

	$R^2 = 0.90$			$R^2 = 0.50$		
	AASB	ARV	ARMSE	AASB	ARV	ARMSE
High collinearity[a]						
CRC $\lambda = 1.0000$	1.1383	0.1725	2.3799	0.3916	0.1836	0.4092
CRC $\lambda = 0.5000$	1.1383	0.1725	2.3799	0.3916	0.1836	0.4092
TVC $t = 2.0860$	0.3097	1.0655	1.2023	0.2540	0.5346	0.6352
TVC $t = 1.0000$	0.0764	0.9910	0.9979	0.0561	0.9232	0.9287
Moderate collinearity						
CRC $\lambda = 1.0000$	1.8241	0.2383	5.9991	0.6156	0.2309	1.1850
CRC $\lambda = 0.5000$	1.8709	0.4183	6.2225	0.6240	0.4040	1.0555
TVC $t = 2.0860$	0.4274	1.6693	1.9502	0.3200	0.8615	1.0522
TVC $t = 1.0000$	0.0782	1.1120	1.1209	0.0672	1.0252	1.0320
Low collinearity						
CRC $\lambda = 1.0000$	3.0560	0.3868	10.5683	1.0220	0.3813	1.5115
CRC $\lambda = 0.5000$	2.7041	0.6141	10.8966	0.8783	0.6124	1.6096
TVC $t = 2.0860$	0.4779	1.3845	1.5656	0.5736	1.0589	1.4288
TVC $t = 1.0000$	0.0605	1.1053	1.1112	0.1384	1.0876	1.1123

[a] High collinearity: $|\Omega| = 0.0045$, $r_{12} = 0.87$, $r_{13} = 0.89$, $r_{23} = 0.91$, $r_{14} = 0.87$, $r_{24} = 0.89$, $r_{34} = 0.91$. Moderate collinearity: $|\Omega| = 0.0930$, $r_{12} = 0.59$, $r_{13} = 0.59$, $r_{23} = 0.63$, $r_{14} = 0.78$, $r_{24} = 0.74$, and $r_{34} = 0.54$. Low collinearity: $|\Omega| = 0.6647$, $r_{12} = 0.34$, $r_{13} = -0.03$, $r_{23} = 0.44$, $r_{14} = -0.02$, $r_{24} = 0.15$, and $r_{34} = 0.13$. Ω is the correlation matrix of X.

With decreasing levels of multicollinearity, the AASB increases using the CRC (table 1). This occurs under conditions of high and low R^2. Particularly distressing is the erratic nature of the bias using the CRC under high R^2 and lower collinearity. Some of the individual estimates were biased to the extent that they were many standard deviations from β_i.

Recalling equations (12) and (13), the CRC does, however, take into account the denominators of the terms in the sum producing the variance expression. Extremely low values of some of the characteristic values, as would be the case in highly collinear situations, coupled with moderate w_{ij}^2 values could result in large gains in precision when deleting components. On the other hand, there is no guarantee that when using the TVC the estimates are more precise than OLS estimates.[10] Again, the results in table 1 exhibit an interesting contrast between CRC and TVC. The CRC yields quite precise estimates relative to the TVC. Under conditions of high or low R^2, the CRC produces an ARV well below unity. As the degree of collinearity decreases, so does the savings in precision as the characteristic roots associated with deleted components increase in magnitude. The TVC, however, generally performs poorly except in the case of high collinearity and low R^2. The individual estimates of β_i using CRC typically had lower variance than the TVC.

As a measure of the relative MSE of CRC and TVC estimates compared with OLS estimates, recall

$$\frac{\text{MSE } b^*_i}{\text{MSE } b_i} = \frac{(\text{bias } b^*_i)^2 + \text{var } b^*_i}{\text{var } b_i}$$

$$= (\text{standardized bias } b^*_i)^2 + \frac{\text{var } b^*_i}{\text{var } b_i}.$$

With the exception of the case of high collinearity and low R^2, the MSE of CRC is greater than the MSE of either TVC or OLS. As the degree of collinearity decreases, the ARMSE of CRC increases. This is particularly true for the case of high R^2. Under the TVC, particularly with $t = 1$, a relatively small bias is introduced, but little precision is gained. This results in estimates that generally exhibit greater MSE than OLS estimates. When R^2 is low and the collinearity high, both the TVC and the CRC have smaller MSE than OLS (table 1).

Table 2 presents in more detail the case

[10] Recall the discussion in the section on t-value criterion. The expression for the variance when using TVC is expressed in symbolic form in equation (22). The explicit expression is an extremely complicated function of the normal and gamma density functions and the critical t-value and is not presented here.

Table 2. Results of Monte-Carlo Experiment with $R^2 = 0.50$ and Sample Generalized Variance = 0.0045

Parameter	Criterion	$\bar{b}^*_i$	STD b^*_i	$\frac{\text{MSE } b^*_i}{\text{MSE } b_i}$
β_1	OLS	10.0	45.2	1.00
	$\lambda = 1.0, 0.5$	23.9	4.8	0.11
	$t = 2.086$	20.6	24.2	0.34
	$t = 1.0$	11.2	41.2	0.83
β_2	OLS	27.0	19.0	1.00
	$\lambda = 1.0, 0.5$	9.3	1.9	0.88
	$t = 2.086$	15.5	15.8	1.06
	$t = 1.0$	24.6	18.9	1.01
β_3	OLS	36.0	141.9	1.00
	$\lambda = 1.0, 0.5$	61.5	12.3	0.04
	$t = 2.086$	56.6	78.0	0.32
	$t = 1.0$	50.0	134.6	0.91
β_4	OLS	4.0	263.6	1.00
	$\lambda = 1.0, 0.5$	129.0	25.9	0.23
	$t = 2.086$	68.3	193.4	0.60
	$t = 1.0$	6.9	255.8	0.94

Note: Deletion using either $\lambda = 1.0$ or $\lambda = 0.5$ in this case results in identical estimators (see footnote 9). Simple correlations in this case are $r_{12} = 0.87$, $r_{13} = 0.89$, $r_{23} = 0.91$, $r_{14} = 0.87$, $r_{24} = 0.89$, and $r_{34} = 0.91$.

where PC-OLS exhibits its best performance—the case of low R^2 and high multicollinearity. Except for the estimates of β_2 using the TVC, the MSE's of PC-OLS estimates are lower than the MSE's of OLS estimates.

However, although PC-OLS appears to be better than OLS in the relative MSE sense, there is a question of whether or not any of the estimating procedures result in acceptable estimates; that is, the MSE of a PC-OLS estimate, although small relative to the MSE of an OLS estimate, may still be large in an absolute sense and may contain a large variance and/or bias component.[11] A case in point is the TVC estimate of β_4 using a t-value of 1.0, which exhibits an extremely large variance, although it is better than OLS in the relative MSE sense.

Summary and Recommendations

This particular simulation study and certain theoretical considerations indicate that the principal components regression technique does not perform well when R^2 is high and/or collinearity is low. In this case, estimates produced under the CRC, although more precise than OLS estimates, are biased to the extent that they have larger MSE's than OLS estimates. The TVC generally produces less biased estimates than CRC in this situation, although the gain in precision, if any, is less than when using the CRC. This also results in estimates that, for the most part, have larger MSE's than OLS but smaller MSE's than the CRC. Under conditions of high collinearity and low R^2, either the CRC or the TVC appear to produce more precise estimates with lower MSE's than OLS. The CRC produces estimates with lower variance but greater bias than TVC estimates.

Although in certain cases the PC-OLS estimates may be better than OLS estimates in the MSE sense, they may still be unsatisfactory in the absolute sense. Most of the individual parameter estimates for the cases where PC-OLS exhibits its best performance in terms of relative MSE still have large variances and/or large biases.

While this study does not provide a complete investigation of principal components regression technique using either CRC or TVC, it does demonstrate that this technique is not a panacea for highly collinear data. The PC-OLS estimation technique using either CRC or TVC does not provide a general remedy for the multicollinearity problem. On the other hand, the fact that PC-OLS estimates outperform OLS estimates in terms of MSE in certain situations suggests that the technique cannot be generally considered inappropriate as an alternative to OLS. Judicious application of the PC-OLS technique, as with most biased techniques, would require a priori notions of signs and relative magnitudes of parameter values that could be used to judge the reasonableness of estimates.

It is hoped that by discussing the mechanics of CRC and TVC deletion in PC-OLS estimation, and by presenting some of the strengths and weaknesses of the technique, the applied researcher is better able both to interpret the results of studies using this technique and to judge whether or not the technique would be useful in his own research.

Linear Programming versus Positively Estimated Supply Functions: An Empirical and Methodological Critique

C. Richard Shumway and Anne A. Chang

This paper examines whether supply relations derived from a static profit-maximizing linear programming model can be used as information to explain supply response with at least the same reliability as partial adjustment regression models. Programming estimates of direct supply elasticities of California commodities are compared with estimates from time-series regressions. Differences on individual crops are considerable, but on average the elasticity estimates are comparable. Programming parameters are combined with time-series data to test whether imposing such relative parameters on time-series models need not significantly reduce their predictive ability. This imposition does not reduce predictive ability or significantly improve it.

Key words: linear programming, prediction, regression, supply functions.

This paper evaluates the reliability of linear programming (LP) as a method of estimating supply elasticities and predicting future production levels in a situation where econometric tools are viable alternative methods. LP and positive estimates of the long-run supply functions for fifteen major vegetables and field crops in California are developed for an approximately comparable historical time period. Both direct (i.e., own product) and cross- (i.e., alternative product) price relationships are estimated via LP, but only direct relationships are estimated with single-commodity partial adjustment equations.

After developing both sets of supply relationships, their long-run direct elasticity estimates are evaluated for mean comparability. Subsequently, the LP direct and cross-price parameters are combined with time-series data to test the hypothesis that the imposition of the relative magnitudes of the LP parameters on a time-series regression supply model need not significantly reduce its ability to predict future output levels. Before addressing these objectives, it is useful to digress briefly to outline the basic problem that compels such attention.

Status of Research on Cross-Price Supply Relations

Accurately estimating the responsiveness of commodity supply to price changes is both important and extremely difficult. Much research effort has been devoted to supply analysis using both positive and conditionally predictive estimating procedures.[1] However, most of this work has been concerned with the development of single-commodity supply functions with little explicit regard for the effect of other commodity prices.

While important conceptual and empirical problems remain in understanding direct price effects on supply, even more serious problems limit the understanding of cross-price relationships. Relatively little empirical research has addressed the estimation of cross-price parameters in the supply function. One of the few exceptions is the pioneering work of Pow-

Technical Article 12662 of the Texas Agricultural Experiment Station. The authors wish to thank Hovav Talpaz and Enrique Ospina for analytical contributions and Bruce Beattie, Peter Barry, Richard Boisvert, and the anonymous *Journal* reviewers for many constructive suggestions on the manuscript.

[1] Supply relations that are derived from continuous or stepped production functions by assuming profit-maximizing behavior on the part of producers is given several different labels in the literature, e.g., normative, conditionally normative, and conditionally predictive. Preference for the terminology "conditionally predictive," used in this paper, is originally defended by Hildreth and Castle (pp. 31–32).

ell and Gruen, who imposed the assumption of a constant elasticity of transformation on the production function to reduce the number of supply parameters requiring estimation. Assuming profit-maximizing behavior, conditionally predictive estimates of direct and cross elasticities of supply in Australia were developed for six commodities from time-series data (Gruen et al.).

Among the positive estimates, Just's econometric analysis of eight California field crops is perhaps the most comprehensive. Yet, no more than two alternative product price variables are included in any of his empirical equations.

What is most striking is that the number of conditionally predictive estimates of cross-price relationships derived from LP is also very limited. The S-42 Technical Committee's publication on cotton reports the estimated impact of price changes for one agricultural commodity on the supply of several other commodities. Most other major LP supply studies that have included alternative commodities are limited in focus to no more than two cross-price relationships (e.g., Colyer and Irwin; Helmers and Lagrone; Dean, Johnson, and Carter).

LP is seemingly an obvious analytical approach for comprehensive estimation of cross-price effects because it is a controlled synthetic experiment. Interaction between a wider range of alternative products and production processes than is practical in time-series analyses can be considered. By carefully selecting the manner in which variables are parametrized, the major data problem that plagues positive estimation of cross relationships, i.e., high correlation among independent variables, can be avoided.

Evidence of Unreliability in Conditionally Predictive Estimates

There is little empirical evidence that reliable direct price relationships, let alone cross-price effects, can be estimated with conditionally predictive models, including LP. For example, in a comparative study of supply estimates derived from production functions versus positive estimates, Wipf and Bawden find that (*a*) "Output predictions obtained from the derived supply approach (from production functions) do not exhibit a consistent magnitude or direction of bias—they range from slight under-estimates to extreme over-estimates of actual output, with the latter being the most prevalent" and (*b*) "Both casual observation and directly estimated (positive) supply equations show firms to be less responsive to price changes than indicated by supply elasticities derived from production functions" (p. 177). In a comparison of selected LP supply elasticity estimates with positive time-series estimates for three subsectors, Quance and Tweeten also observe greater variability and generally larger magnitudes in the conditionally predictive than in the time-series elasticity estimates. They conclude that "the LP models are more realistic for showing regional shares of production (based on comparative advantage) than for showing the absolute level and elasticity of supply" (p. 7).

The issue of evaluating reliability is fundamental since it is generally easier to obtain estimates of cross-price supply relationships from conditionally predictive models, especially LP, than from positive models. However, before placing confidence in LP cross-price estimates, one must first be convinced that the direct price estimates are reliable.

Methodological Critique

It is intuitively apparent that estimates obtained from positive time-series models differ from those derived from LP, but it is not apparent a priori that the positive estimate should in all cases be more reliable than the LP estimate. Because the positive estimate is based on fitting a linear regression to historical data with least-squared error, one expects it to describe what has actually occurred in the past and, if past policies and relationships among variables remain stable, to predict more accurately than the LP-derived estimate. Positive estimates may neither accurately describe the past nor accurately predict if one or more of the standard statistical assumptions are violated, e.g., errors in data measurement or aggregation, high correlation among independent variables, omission of relevant variables, or incorrect anticipation of the form of the relationship.

In contrast, using a combination of historical and synthetic data and imposing a behavioral assumption (typically profit maximization), linear programming describes what "should" have happened rather than what did happen. Perhaps its most important strength is that it can simulate the effects of exogenous forces and policies for which historical obser-

vations are not available. But problems faced with LP in either correct description or prediction are also substantial (Stovall). Much of the data necessary for LP supply model development, e.g., crop budgets and resource restraints, are difficult to adequately verify external to the model. Data validity can often be tested only indirectly by comparing initial model results with a historical referent. It is difficult to prevent important aggregation errors when cumulating representative farm LP results. Since profit maximization is not the only goal of producers, models that fail to consider risk and nonmonetary objectives in the analysis may abstract seriously from reality. Due to the stepped nature of the LP production function, it is possible to obtain perfectly elastic or inelastic estimates of supply over small price ranges.

Although LP analyses abstract from reality, the question remains whether their previously noted unreliability in estimation is inherent in either their synthetic nature or behavioral assumption or whether it is due to the particular examples cited.[2] In the Wipf and Bawden and Quance and Tweeten comparative studies of conditionally predictive and positive supply estimates, the commodity comparisons are limited, the spatial and temporal dimensions of the models not entirely comparable, and the analyses rather casual. Consequently, the current analysis develops both positive and LP estimates of the supply relations for a large number of commodities in the same geographic region and for essentially the same time period.

Linear Programming Estimation

Model Formulation

Static LP resource allocation models were developed previously for California (Shumway et al.). The state is divided into ninety-five homogeneous production areas based on similarities in soil, climate, and water resources. Acreage suitable and potentially available for crop production in each production area during the period 1961–65 is inventoried. Estimates of per acre yield and non-land production costs for each of fifteen commodities and commodity groups, representing 79% of total crop acreage, are developed for each area for that period. Acreage in excluded high-value crops (orchard crops and minor vegetables) and in nonagricultural uses is deducted from the acreage inventory. Maximum individual crop acreages are limited only by land and water resources available and by rotation requirements. Hence, production changes are permitted within a long-run firm adjustment period with constant technology—no short-run restraints such as capital, farm size, labor, or management are imposed.

The objective function of the model is converted from cost minimization to profit maximization with product and nonland input prices given so that the parametrization could be performed on the independent supply variable, price. Based on the premise that expected price in any year is equal to lagged actual price, production costs are adjusted so that constrained model results approximate actual 1961–65 output of each commodity at 1960–64 prices.[3] Parametric programming is then applied to chart the effect of alternative prices on output levels.

The total land resource available for producing the fifteen commodities/commodity groups is assumed to be limited at the model's requirement for average 1961–65 output of these commodities. Actual harvested acreage of these crops during 1961–65 is less than in some years prior to 1955 but approaches the upper limit on subsequent acreage harvested. Beginning with actual 1960–64 average prices for all commodities, one price is parametrically changed by intervals of approximately one-tenth of the difference between high and low deflated prices during 1950–73.[4] This procedure is repeated by parametrically increasing and decreasing the price of each commodity in sequence while holding all other prices constant. Thus, observations of price changes for each commodity and derived optimal output levels for all fifteen commodities are obtained.

The parametric programming results are treated as though they are independent obser-

[2] Considerable attention has been devoted in recent years to methods for making programming models produce results more in line with results observed in the real world. These efforts have included incorporation of flexibility constraints into recursive linear programming systems (e.g., Shaller and Dean) and specification of more realistic behavioral properties (e.g., Boussard, Boussard and Petit). The scope of this paper, however, is confined to an evaluation of results obtained only from more conventional static profit-maximizing LP.

[3] Production cost budgets representing approximately the top 20% of producers are scaled upward across production areas for each commodity.

[4] California product prices (California Crop and Livestock Reporting Service, all dates) are deflated by the USDA (1973, 1974) index of prices paid by farmers for inputs (1960–64 = 100).

vations.[5] Because of the sequential nature in which prices are changed, the data are segmented and simple linear regressions of output are fit to relevant data subsets in which the price of only one commodity varied:

$$(1) \qquad Y_i = a_{i0} + a_{ij}P_j + \mu_{ij},$$

where Y_i is the derived output vector of commodity i, P_j is the parametrized price vector for commodity j (all other prices held constant), and μ_{ij} is the disturbance term. At the suggestion of one of the reviewers, output is also regressed as a quadratic function on own price:

$$(2) \qquad Y_i = a_{i0} + a_{ii}P_i + \alpha_{ii}P_i^2 + \mu_{ii}.$$

$\bar{R}^2$ values of the own price equations are improved in most cases by inclusion of the quadratic term.

LP-Derived Elasticity Estimates

Estimates of the long-run supply elasticities for each commodity/commodity group are computed at the average 1961–65 output levels and lagged representative crop prices, which are listed in table 1. These conditionally predictive direct and cross-price elasticity estimates are reported in table 2. Except for cotton, all direct elasticities derived from the linear equations exceed 1.0, and most are considerably higher. The direct elasticities derived from the quadratic equations are typically greater than those from the linear equations. Cross elasticities are positive only between barley price and grain sorghum supply, grain sorghum price and barley supply, and broccoli price and lettuce supply. These crops are frequently doublecropped so positive cross elasticities are reasonable. Both direct and cross elasticities tend to be higher for commodities with relatively small 1961–65 acreages (i.e., all vegetables, corn, and sugar beets). These estimates are probably overestimated due to the aggregate nature of the model. Although there are up to ninety-five segments on the model's stepped production function for each commodity, each step may be very large for the smaller crops. Therefore, we have less confidence in the reasonableness of the LP elasticity estimates for the minor than for the major crops.

To determine whether the extremely elastic

[5] The use of regression analysis is reported here with two qualifications: (*a*) the observations are not really independent since prices are not selected randomly and (*b*) the price selection procedure implies a uniform distribution of prices between the high and low observations. Since the typical distribution of actual prices is more bell-shaped, use of the parametric programming observations here gives undue weight to the outliers.

Table 1. Average 1961–65 Output and 1960–64 Price of California Vegetables and Field Crops

Representative Commodity (Commodity Group)	Commodity (Commodity Group) Output, Average 1961–65[a] (1,000 Units)	Representative Commodity Price, Average 1960–64 ($/Unit)
Alfalfa hay (ton)	6,223	24.38
(and seed)	(6,837)

supply functions for crops with smaller acreages is a local phenomenon of the LP model structure in the vicinity of 1960–64 prices, their price ranges are widened arbitrarily to five times the 1950–73 range. Ten additional observations of crop output are obtained by further parametric price changes for each of these eight crops over the expanded range. Regression equations are reestimated from this expanded data set, and elasticities are again computed at mean 1961–65 output levels and lagged prices. The results are reported in table 3.

Direct elasticities for crops with expanded price ranges are substantially lower in all cases than previously for both linear and quadratic formulations, suggesting that the high elasticities are due at least in part to the limited range of prices considered. The direct linear estimates now range from 0.8 to 9.6, as compared with a range from 0.8 to 142.5 previously. The direct quadratic estimates are now 1.2 to 29.8, as compared with 2.1 to 203.1 previously.

Positive Estimation of Direct Supply Relationships

Model Formulation

Using annual time-series data for 1950–73 (i.e., the same data as previously used to specify the initial range for the LP parametric analysis), a simple partial adjustment supply model is hypothesized for each of the fifteen representative commodities:

$$(3) \qquad y_t = b_0 + b_1 p_{t-1} + b_2 y_{t-1} + \mu_t,$$

where y is output, p is product price deflated by the index of prices paid for inputs, t is year, and μ is the disturbance term. Recognizing that the output of some commodities has changed markedly over the twenty-four-year period due to technology and other changes, a second model that includes a trend variable is also estimated:

$$(4) \quad y_t = b_0 + b_1 p_{t-1} + b_2 y_{t-1} + b_3 t + \mu_t,$$

where t is year (1950 = 1).

Since an in-depth investigation of the supply relationships for each crop was not conducted, it is unlikely that all supply systems are adequately explained by either of these model structures. Therefore, in lieu of hypothesizing and testing many other alternative models, rather rigorous conditions are specified for accepting these models as adequate explanatory structures, and the empirical evaluation of direct elasticities is restricted to those equations that are not rejected. Only those equations are considered for empirical evaluation that exhibit both parameter signs and magnitudes consistent with a priori expectations (i.e., $b_1 > 0$, $0 \leq b_2 < 1$) and b_1 coefficients significant at the 5% level. No preferential treatment is given to either model. If the empirical results of both pass the conditions, both equations are reported for that commodity. The average of their long-run direct supply elasticity estimates is compared with the linear programming estimates.

Equations in which the lagged dependent variable appears as an independent variable frequently exhibit serially correlated disturbance terms and also bias the test for serial correlation in OLS estimation. Consequently, the less restrictive Cochrane and Orcutt model with the Cooper transformation is used to obtain parameter estimates and standard statistics with asymptotically desirable properties for these equations.

Positive Elasticity Estimates

For nine of the fifteen commodities, at least one time-series regression equation satisfies the a priori conditions. Unsatisfactory results are obtained with both hypothesized models for the remaining six crops: alfalfa hay, grain sorghum, rice, safflower, asparagus, and processing tomatoes. The unsatisfactory results from these models are not surprising for the two perennial crops—alfalfa hay and asparagus. A more complex investment model is likely needed to adequately explain planting response for perennials. The poor showing of the partial adjustment models for the other four crops is also understandable. Rice and grain sorghum are produced under commodity programs, safflower appears during this period as an emerging agricultural industry, and production practices for processing tomatoes shifted midway through the time series from labor intensive to a mechanized harvest. (See Chern for a recent analysis of processing tomato supply response.)

For the other nine crops, the estimated parameters and long-run supply elasticity computed at average 1961–65 output and lagged price are reported in table 4 for satisfactory

Table 3. Conditionally Predictive Estimates of Long-Run Elasticities of Supply, Expanded Data

Commodity	No.	Linear Function, Elasticity with Respect to the Price of															Quadratic Function, Own Price Elasticity

	4	123,769 (5.02)	235 (2.24)	0.253 (5.21)	−3,534 (−12.44)	0.82	−0.34	|0.9|	0.4
Sugar beets	4	−13,325,700 (−3.59)	1,140,900 (4.07)	0.442 (4.61)	213,757 (12.13)	0.78	−0.34	|0.8|	4.0
Broccoli	4	−107,507 (−3.23)	677 (3.81)	0.596 (10.97)	2,963 (11.71)	0.91	−0.36	|0.9|	3.1
Cantaloupes	3	−186,592 (−3.03)	2,264 (3.92)	0.953 (14.76)	—	0.76	−0.72	|0.2|	12.3
	4	−184,466 (−2.93)	2,252 (3.80)	0.948 (14.40)	56 (4.60)	0.74	−0.71	|0.9|	11.0
Lettuce	4	−212,436 (−1.61)	3,626 (2.94)	0.862 (23.08)	9,432 (10.16)	0.95	−0.41	|0.9|	1.7
Potatoes	3	−350,778 (−1.74)	8,701 (6.04)	0.939 (8.17)	—	0.69	−0.45	|0.4|	4.4
	4	−350,068 (−1.78)	8,654 (5.88)	0.942 (8.43)	−244 (−9.44)	0.67	−0.45	|0.4|	4.6

Note: t-values are in parentheses.

equations.[6] All but two of these long-run supply elasticity estimates are greater than 1.0. Elasticity estimates range from 0.4 to 25.2, with half between 3.0 and 6.0. Where both equations satisfy the stipulated conditions for a commodity, except for dry beans, elasticity estimates from the two equations are similar.

$\bar{R}^2$ values are mixed, exceeding 0.9 for four equations and being less than 0.7 for five. Correlation among independent variables is considerably higher for equation (3) than for equation (2) regressions, generally being in the 0.8 to 0.9 range for equation (3) and 0.1 to 0.4 range for equation (2). Ranging from −0.72 for cantaloupes to 0.90 for corn, the autocorrelation coefficient ρ is positive for four of the equations and negative for ten. Consequently, there is evidence that autocorrelation of errors would be substantial in OLS estimation of each of these equations.

Direct Elasticity Comparison

The LP-derived long-run direct supply elasticity estimates differ substantially from the positive estimates. Simple correlations between both pairs are less than 0.1. However, as many of the LP estimates are lower than the positive estimates as are higher; i.e., for the nine representative crops, six from the linear and three from the quadratic LP-derived equations are lower than the positive estimates (see table 5). The average elasticity is 5.4 for the positive estimates, 2.7 for the linear LP estimates, and 8.3 for the quadratic LP estimates.[7] The average (5.5) of both sets of LP-derived estimates for these nine crops is only slightly higher than the average of the positive estimates.

The similarity of the average magnitudes is particularly striking when it is realized that important variables are omitted from the time-series equations, and the likely effect of at least one important set of omitted variables is to bias the direct elasticity estimate downward. Most agricultural product prices are positively correlated. For example, of the 105 pairwise relations between the fifteen representative commodities in this analysis, deflated 1950–73 annual California prices are positively correlated in eighty-eight cases. In

[6] Long-run elasticities are derived from the partial adjustment model by dividing the short-run elasticity estimates by $1.0 - b_x$.

[7] The mean direct elasticity for these nine crops from the LP with initial data is much higher—42.4 (linear estimate) and 57.1 (quadratic).

Table 5. Comparison of Linear Programming and Positive Estimates of Long-Run Direct Elasticities of State Supply

Representative Commodity	LP-Derived Estimate for Community Group, Expanded Data, Shumway-Chang		Time-Series Estimates for Representative Commodity	
	Linear	Quadratic	Shumway-Chang[a]	Just
Barley	4.8	5.0	3.8	20.0
Corn	1.0	4.0	5.8	5.4
Cotton	0.8	2.1	1.1	0.2
Sugar beets	2.2	7.4	4.0	1.0
Dry beans	4.0	14.1	12.8	—
Broccoli	7.7	26.5	3.1	—
Cantaloupes	1.4	5.4	11.7	—
Lettuce	2.3	8.6	1.7	—
Potatoes	0.3	1.2	4.4	—
Alfalfa	5.4	11.6	—	0.2
Grain sorghum	9.6	17.9	—	4.3
Rice	6.0	8.5	—	0.2
Wheat	4.8[b]	5.0[b]	—	51.1
Mean				
Barley-potatoes (9 crops)	2.7	8.3	5.4	—
Barley-sugar beets and alfalfa-wheat (8 crops)	4.3	7.7	—	10.3
Barley-sugar beets (4 crops)	2.2	4.6	3.7	6.7

[a] Average of equations (2) and (3) when both meet the specified conditions.
[b] Wheat is grouped with barley in the LP analysis. Elasticities of both crops are assumed to be the same here.

addition, the positive correlations are generally of larger magnitude than the negative. Omission of a relevant competitive product price variable from the time-series equation biases the estimated direct elasticity of supply downward.

The effect of omitting policy variables is less clear a priori. In his supply analysis of eight field crops in six California regions, Just accounts for commodity programs, selected alternative crop prices, and risk. Aggregating across regions, we calculated his direct acreage supply elasticity estimates at mean 1960–64 prices. These are listed along with the LP and time-series estimates in table 5. Elasticity estimates based on his equations are on average higher and more varied than either these time-series or LP-derived estimates, suggesting that the direction of bias due to omitted variables may be commodity specific.

The standard deviation of elasticities across crops is higher for the time-series (4.1) than for the linear LP-derived estimates (2.4) but lower than for the quadratic LP-derived estimates (7.8). Since the mean magnitudes and variability across crops for the LP are similar to the time-series estimates and since many of the LP estimates are lower than the time-series estimates, this comparison of direct supply elasticity magnitudes does not support the findings of Quance and Tweeten and Wipf and Bawden that conditionally predictive supply elasticity estimates are generally larger and more variable than time-series estimates. However, the results in terms of individual crops are inconclusive.

Predictive Accuracy

Finding the LP-derived and time-series direct elasticity estimates reasonably comparable only on average but not in individual instances, the following hypothesis was subjected to test: Imposition of the relative magnitude of LP direct and cross-price parameters on a time-series supply model need not significantly reduce its ability to predict future output levels. Since the most recent data used in the estimation of the time-series equations are for 1973, 1974 and 1975 are used as the projection period. Because of rapidly changing economic conditions, testing model predictive accuracy for these years constitutes a very rigorous test.

Predicting with the time-series equations is straightforward. Output for 1974 (1975) is predicted by inserting 1973 (1974) price and output into the relevant equations with parameters previously estimated and solving for 1974 (1975) output. Use of the LP-derived supply equations for prediction is not so clear cut. Assuming profit-maximizing behavior, the LP provides estimates of the long-run desired output levels at alternative prices, and these estimates then become observations for fitting regression equations. Since long-run output levels are never observed in the real world, no observations exist against which to measure the predictive accuracy of the LP-derived output projections. Therefore, one could not simply insert 1973 (1974) prices into the LP-derived supply equations, predict output, and meaningfully compare that prediction with actual 1974 (1975) quantity.

Model for Predicting with LP-Derived Price Parameters

The LP-derived price parameters can be used, however, as prior information for fitting partial adjustment supply models that can be used to predict output. In order to maintain greatest structural consistency with the positive equations, only the linear LP-derived price parameters are considered as prior information.[8] First, a new composite variable is defined from the linear LP-derived price parameters and the time series of crop prices:

$$p'_{it} = \sum_{j=1}^{n} a_{ij} p_{jt}, \tag{5}$$

where p'_{it} is the composite variable for commodity i in year t, a_{ij} is the LP-derived estimate based on expanded data of the jth commodity price parameter in the supply of the ith commodity, and p_{jt} is the deflated price of the jth representative commodity in year t. Partial adjustment supply models are then fit to annual output and composite price data for 1950–73. The models are comparable with the two positive models previously fit to single commodity data:

$$y_{it} = b_{i0} + b_{i1} p'_{i,t-1} + b_{i2} y_{i,t-1} + \mu_{it} \tag{6}$$

[8] We also estimated predictive equations using the quadratic LP-derived price parameters as prior information. These equations satisfy the previously specified conditions for "acceptable" explanatory models for thirteen of the thirty equations (as compared with fourteen for the positive and five for the linear LP models). They predict more accurately than the linear LP equations for half the crops and perform comparably in mean predictive ability.

and

$$(7)\quad y_{it} = b_{i0} + b_{i1}p'_{i,t-1} + b_{i2}y_{i,t-1} + b_{i3}t + \mu_t.$$

After estimating the parameters of these equations, 1974 (1975) output is predicted by inserting 1973 (1974) output and composite price data into each equation. Because they embody the relative price parameters from the LP analysis, they are referred to subsequently as "LP time-series" equations. Estimated parameters are reported in table 6 for the same nine crops as the positive estimates are previously reported. Inclusion of the prior information does not improve the explanatory power of most equations. Fewer own price parameters are significant at the 5% level, and $\bar{R}^2$ values are reduced for as many equations as they are raised (eight of the thirty equations).[9]

[9] An alternative model was also developed for combining the LP results as prior information in a time-series regression. Based on the adaptive expectations premise, a nonlinear search procedure (Talpaz) is used to obtain maximum likelihood estimates of the composite price parameter and each product's price expectation coefficient. Both models are used to develop predictions based on LP-derived price parameters obtained from a stepped linear regression estimation. Because of the nonlinear search, that model is more expensive to solve than the partial adjustment model, and improved predictions result for only four commodities.

At the suggestion of one of the reviewers, the supply equations based on the LP parametrization subsequently are reformulated using simple regression, as reported in this paper. However, because of the expense and lack of predictive improvement from use of the adaptive expectations model in the earlier case, the parameters of that model are not reestimated using the new LP-derived price parameters. That model is developed and the empirical results of the earlier estimation using both models are reported in Shumway and Talpaz.

Empirical Comparison of Predictions

The accuracy of the best predictor from each set of equations, i.e., positive equation set and LP time-series set, is compared for individual commodities without regard to whether a priori conditions concerning parameter signs or magnitudes have been satisfied. The percentage of error in the best prediction from each set is recorded for the fifteen commodities in table 7. For 1974 the error ranges across crops from 2.1% to 38.6% for the best LP time-series predictions and from 0.4 to 43.3 for the best positive predictions. For 1975 it ranges from 0.9 to 39.0 for the LP time series and from 0.8 to 57.6 for the positive predictions.

The predictive accuracy of the LP time-series equations is exactly the same as the positive equations for cantaloupes, since the only prior information available from the LP-derived equations is the direct price coefficient. With the LP coefficient providing no restriction nor additional information to the time-series equations, the LP time-series equations are exactly equivalent to the positive equations in that instance.

The best predictor of the LP time-series equations is less accurate than the best of the positive predictors for nine commodities in 1974 and eight commodities in 1975. The LP prediction is considerably better than the positive prediction for two commodities in 1974 and five in 1975 and is much worse for four commodities in 1974 and three in 1975. Mean accuracy of the best LP time-series predictions is a little worse than the mean of the best positive predictions in 1974 but is considerably better in 1975. At the 10% confidence level the mean predictive error of the best conditionally predictive estimate is not significantly greater than the mean error of the best positive estimate in 1974 ($t = 0.2474$) nor significantly lower in 1975 ($t = -0.7382$). Consequently, based on 1974 and 1975 supply predictions, little evidence is found to support the Wipf and Bawden and Quance and Tweeten observations that conditionally predictive estimates tend to be less reliable predictors than the positive estimates of supply. In general, combining LP direct and cross-price supply parameters with time-series data does not substantially reduce the predictive accuracy of the time-series equations. Neither does it substantially improve their predictive accuracy nor their explanatory power.

Conclusions

Linear programming provides a feasible method for estimating both direct and cross

elasticities of supply. It is presently difficult to use positive models to systematically estimate major cross-price effects. However, linear programming estimates are limited in that they are generated in the context of assumptions and model specifications underlying the linear model. The closer these assumptions and model specifications approach an accurate reflection of the decision environment for agricultural producers, the more valid the results expressing supply relationships are likely to be. Conversely, the less they reflect the decision environment, the less valid their results are expected to be.

This comparison of supply elasticities highlights a high degree of comparability in the average magnitude of direct elasticites but a low degree of comparability for individual crops, between the profit-maximizing LP and the positive time-series estimates for California vegetables and field crops. When the LP-derived parameters are used as prior information in time-series regressions, they do not significantly reduce the accuracy of those equations in predicting 1974 and 1975 supply levels. These findings provide direct contrast to earlier studies that conclude that conditionally predictive supply relationships generally result in larger and more variable estimates of the direct elasticity and less accurate predictions of actual supply levels than positive supply equations. The conditionally predictive estimates in the current study are derived from an LP model designed with profit maximization as the presumed single goal of producers (i.e., without riskiness identified as a variable of concern), with perfect competition imposed as the underlying organizational form of the industry, and with a static perspective without flexibility constraints or other conditions imposed on the adjustment path.

The failure of the prior information to significantly increase either the explanatory power or the predictive accuracy of the time-series regressions is in itself a negative find. Although the inclusion of prior relative estimates of the cross-price parameters in the time-series equations does not hurt, it does not help much either. Apparently, greater realism in the LP's specification of producers' behavioral properties and environment is required to produce real world results that improve substantially on simple econometric models where the latter are also appropriate.

Availability and Shipment of Grain for Survival of a Nuclear Attack

Carsten M. Haaland

It is assumed that at least 90% of the American population would survive the direct effects (blast, fire, and initial nuclear radiation) of a nuclear attack of 6,600 megatons if about 90 million people were relocated from high-risk areas during a crisis period preceding the attack. If the survivors from the direct effects are protected from radioactive fallout by suitable shelters, the remaining major problem affecting survival will be adequate food. This paper indicates that sufficient grain stocks and transportation will likely be available after the attack to assure survival of the American population.

Key words: grain stocks, linear programming, nuclear attack, survival, transportation.

Imagine a hypothetical situation in which a confrontation between the United States and the Soviet Union results in a massive evacuation of cities in both countries during the crisis period, and this is followed by an all-out nuclear war in which the United States is hit with 6,600 megatons as shown in figure 1.[1] The circles indicate areas of blast overpressure exceeding 2 pounds per square inch above atmospheric pressure, an overpressure that would cause severe damage to most wood-frame buildings (Glasstone). The Soviet Union has the capability of delivering such an attack with its current arsenal of intercontinental ballistic missiles (ICBM's). Furthermore, the Soviet Union has developed an elaborate civil defense to guarantee survival of its people that relies on evacuation as the principal measure of protection (Egorov, Shlyakhov, and Alabin).

Can the U.S. survivors of the nuclear attack continue to survive through the postattack situation? It is assumed that, because of effective relocation from high-risk target areas (such as large cities, industrial and military complexes) to rural areas of about 90 million people during the crisis period and also because of suitable protection from fallout, over 90% of the U.S. population could survive this attack (Haaland, Chester, and Wigner). Suitable protection from fallout requires shelters that not only provide adequate shielding against radiation but also are adequately equipped with food, water, medical supplies, suitable ventilation, radiation survey meters and dosimeters, two-way communications (either radio or telephone), and at least one AM portable radio receiver.

Under these assumptions, one of the most severe postattack problems will be the shortage of food. In most areas there apparently will be less than two to four weeks of reserve processed food (Billheimer, Jones, and Myers), and much of this food will be consumed during the first two weeks after the attack. Most of the food in the form of livestock and poultry will become unavailable, either because much of the stock will be killed by fallout, for which little protection is being provided, or it will be impossible to process the livestock because of the lack of transport facilities and/or processing plants at convenient locations. Many of the surviving food-processing plants will be unable to operate because of power outages or because of intense radiation from fallout.

The outcome of the cumulation of these effects on the food situation in the U.S. is uncertain. Some of the surviving processing plants may be capable of tripling their output of products depending on grains such as flour,

The views expressed are those of the author and do not necessarily represent those of the Defense Civil Preparedness Agency or the Energy Research and Development Administration. The author is indebted to Philip Coleman for development of the computer-drawn maps and to Gary Westley and Philip Coleman for development of the linear programming model for shipment of grain.

[1] This attack size and configuration is provided by the Defense Civil Preparedness Agency for planning purposes only.

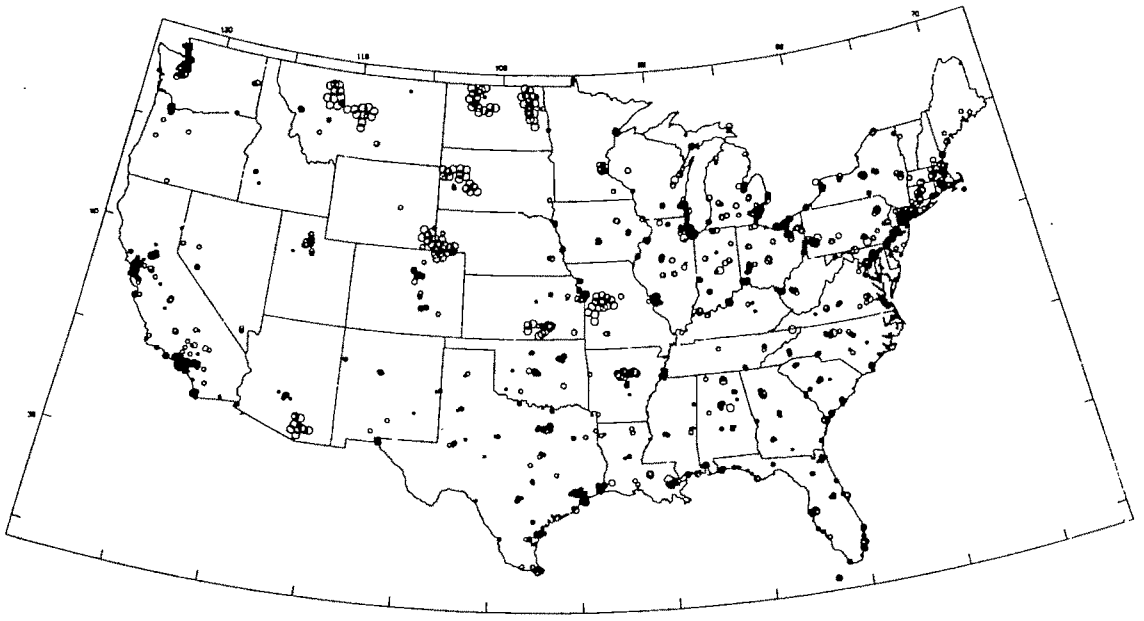

Figure 1. Hypothetical nuclear attack for crisis relocation planning. Circles show areas covered with 2 psi or greater overpressure from blast; number of delivered weapons: 1,444; total yield delivered: 6,559 megatons.

corn meal, corn oil, margarine, and secondary products such as bread, cereals, noodles, and spaghetti. In many areas, the absence of adequate food-processing plants may require that people turn to primitive methods of preparation of raw grains in order to survive. Many old recipes have been rediscovered as a result of the general trend back to nature and self-sufficiency in the United States, and some of these recipes and others have been tested and are described by Kearny.

The innate capability of grain to be stored almost indefinitely with little care and without spoilage, and its suitability as a nearly complete food for human consumption, has drawn the attention of strategic planners throughout the entire known history of man. One of the principal slogans of the late Mao Tse-tung, echoed through Red China and incorporated in its Constitution, is "Dig tunnels deep, store grain everywhere, prepare for war and disaster." The Soviet Union is also preparing to store massive quantities of grain (Kuznetsov) and is currently in the last five-year stage of a "shock construction" project to build storage facilities for 2.5 billion bushels of grain, enough to supply the Soviet population with 300 days of food. It is therefore appropriate that grain should be considered as a survival item for the United States.

Availability of Grain in the United States

The United States has consistently produced more grain annually than required for survival by its population (figure 2). The amount required per day for survival is estimated to be an average of two pounds of grain per person, based on a requirement of an average of 3,000

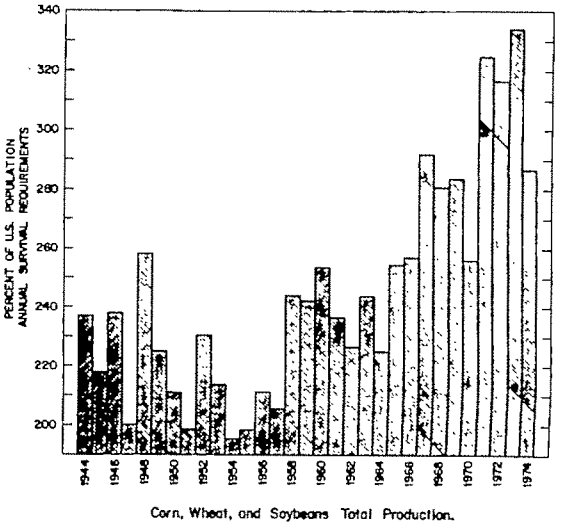

Figure 2. Total production of corn, wheat, and soybeans as a percentage of U.S. population minimum survival requirement

calories per day (Garland). The extra quantity of grain produced is usually primarily for feeding livestock and for export; hence, the amount of grain on hand does not always exceed the annual minimum survival quantity. From figure 3, it is apparent that 30% to 40% of the annual U.S. grain production for each of the years from 1965 through the present would be adequate for the minimum annual survival quantity.

Nearly all the grain stored on farms and 50% to 70% of the grain stored off farms, depending on the season, would not be affected by a nuclear attack. Grain stored off farms is distributed among local town and county elevators, warehouses, processing plants, and large central terminals. Many processing plants and most of the large terminals would be destroyed by the nuclear attack, but the bulk of off-farm storage is in the local elevators in small towns, which would not be affected by the blast and fire of nuclear weapons detonated on major targets. Covered grain is safe for human consumption even if exposed to radiation from fallout in the surrounding environment.

On-farm stocks by themselves have been adequate for at least six months survival supply for the nation during the spring and summer months for all years since 1954. If a nuclear attack occurred during the spring or summer, the stocks on farms would be adequate for survival through September or later. The harvest, although partially destroyed by fallout and possibly damaged by ultraviolet radiation resulting from ozone depletion due to nuclear war (National Academy of Sciences), would provide adequate additional food reserve through the next harvest.

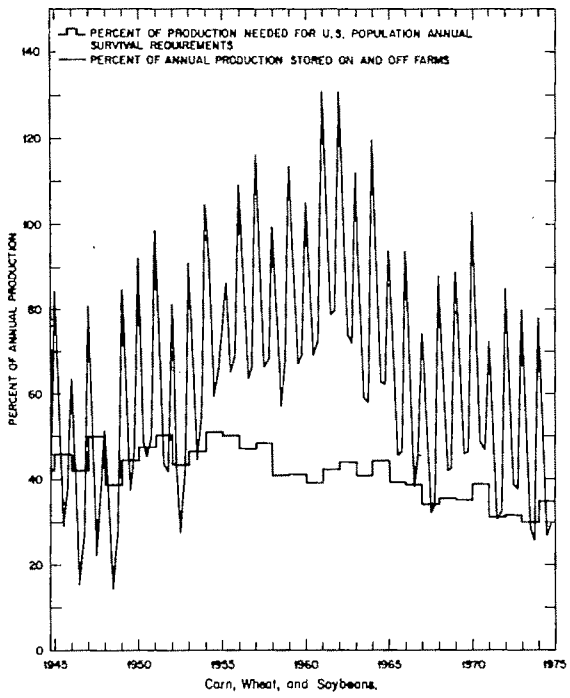

Figure 3. U.S. grain storage relative to survival requirements

Plant responses to irradiation, such as survival, growth inhibition or stimulation, and seed or grain yield, are dependent on dose, dose rate, plant species, type of radiation, and the developmental stage of the plant when irradiated. Killion and Constantin calculate that the fallout gamma dose required to reduce the yield to 50% is 2 to 4 kilorads in wheat and corn and 8 to 12 kilorads in soybeans. Crops are planted at different times at different latitudes. Hence, if the attack occurs on a certain day, virtually simultaneously as far as crops are concerned, crops that have just emerged from the ground at northern latitudes will be more severely affected than those at more southern latitudes that have attained a good stand, or those in the far north that have not yet emerged from the ground.

With these factors under consideration, estimates can be made of the average yield over the entire United States for various fallout conditions for an attack hypothesized to occur in the month of June, at which time the effect of fallout on crops will be most severe (Brown and Pilz). It is assumed, based on data by Killion and Constantin, that when the unit-time reference dose rate R_0 is less than 50 roentgens per hour, the crops are unaffected, when R_0 exceed 1,000 roentgens per hour, the yield is reduced to zero, and when R_0 is in between 50 and 1,000 roentgens per hour, the normal yield is multiplied by the crop yield reduction factor Y, given by $Y = \alpha - \beta R_0^{0.75}$ in which $\alpha = 1.118, \beta = 6.29 \times 10^{-3}$, and Y varies between 0 and 1 for values of $50 \leq R_0 \leq 1{,}000$. This function gives a 50% yield for 2 kilorads exposure, which is conservative according to the Killion and Constantin data.

In order to estimate the crop yield, a specific fallout condition is assumed as shown in figure 4 by contours for five levels of the unit-time reference dose rate on the United States resulting from the hypothetical attack described earlier. The effective wind speed for transport of the fallout particles is assumed to be from the west at 20 miles per hour in this

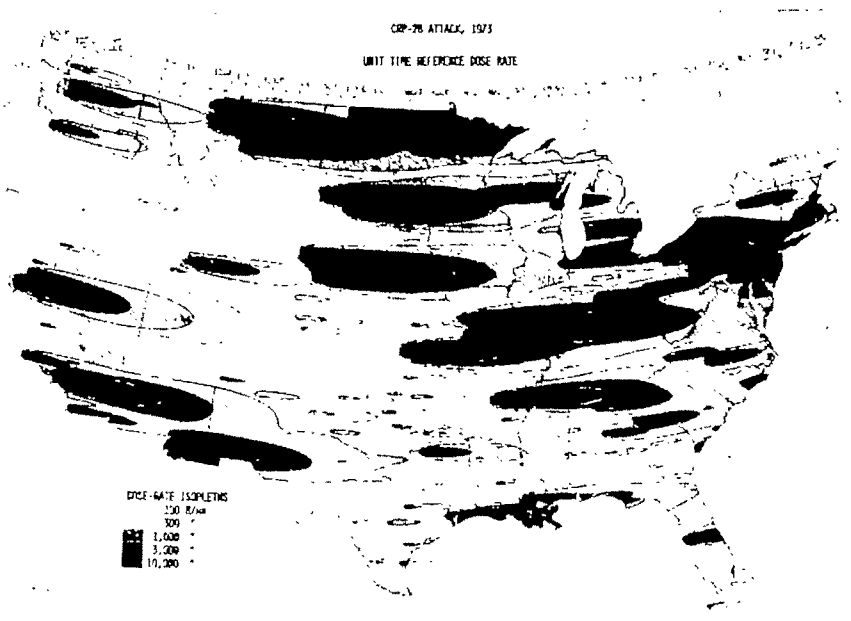

Figure 4. Five contours of possible fallout radiation resulting from a hypothetical nuclear attack

particular case. The crop yield reduction factor Y is applied to the U.S. crop data per county for 1973, as provided to Oak Ridge National Laboratory on computer tape by the Statistical Reporting Service, U.S. Department of Agriculture, and with R_0 given by county from the hypothetical attack. It is estimated that for this particular attack with its special wind conditions, the total crop production will be reduced to approximately 43%, from 6.5×10^{11} pounds to 2.8×10^{11} pounds. The additional loss due to increased ultraviolet radiation from ozone depletion and from reduced temperature due to dust from nuclear war (comparable with the volcanic eruption of Krakatoa) cannot be estimated at present because of inadequate knowledge of the extent of these effects. In comparison with this estimate of 43% survival of total grain yield, calculations by the Federal Preparedness Agency of the General Services Administration indicate a survival of 49% to 50% (private communication), based on a much more sophisticated model developed by Ryan, Garza, and Brown.

For planning purposes, grain stocks on farms and in rural elevators are assumed to be the major source of food required for survival in the postattack period. As seen from the data presented, this source is adequate to supply the relocated population until the following harvest, under most circumstances readily foreseen. It is also assumed that these grain stocks are located primarily in the counties in which they are produced. The location of grain-rich and grain-poor BEA's (business economic areas) in the United States can be qualitatively assessed by the computer-drawn map shown in figure 5, which shows the total quantities of all major grains produced in each BEA of the coterminous United States in 1973, according to USDA figures. A comparison with figure 6, which shows the distribution of relocated people by county according to the ADAGIO program (Schmidt) based on preliminary DCPA (Defense Civil Preparedness Agency) planning, reveals that some regions, such as peninsular Florida, northeastern United States, and parts of California, have a large number of people and are also grain poor. These maps indicate that large quantities of grain may have to be shipped during the first few weeks after the attack in order to avoid massive starvation. It will be more desirable to move grain rather than people, in order to reduce to a minimum the number of people exposed to radiation from fallout. In this situation certain transport workers will be asked to risk exposure to doses of radiation that will not be immediately hazardous but may reduce their average life span and/or increase the incidence of late-life leukemia among them (Haaland, Chester, and Wigner). This situation could be largely avoided if the

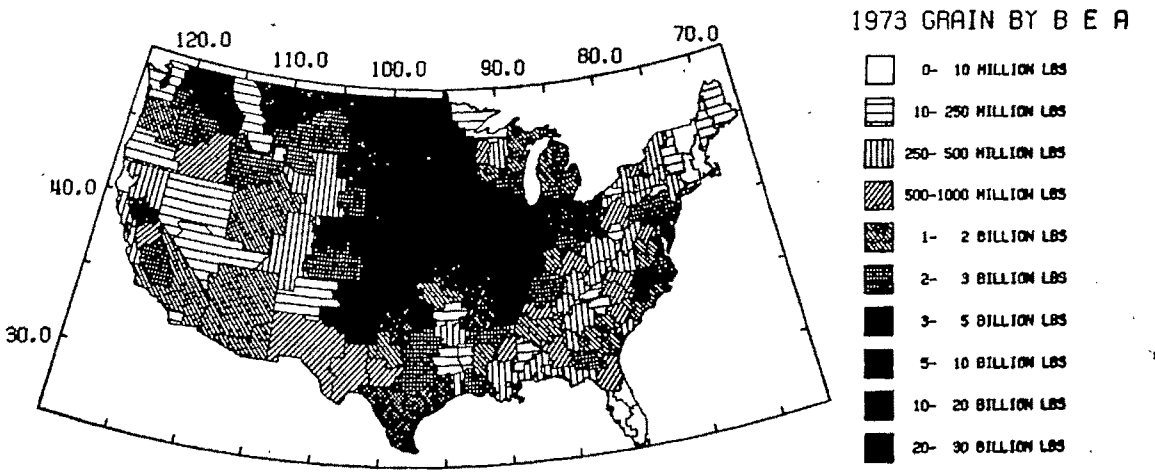

Figure 5. Distribution of production of grain in 1973 by business economic areas. Data source: USDA.

evacuation plans take into account the location of grain stocks in addition to avoidance of high-risk areas, or if the grain is moved and stored before the crisis, as recommended by Garland.

A closer analysis of the actual data shows that 143 counties, containing a total of about 19.8 million people, mostly relocated population, have no grain stocks whatsoever; in other words, the number of food-days available from local grain stocks is zero (figure 7). In other locations, about 26 million people are located in counties in which the local grain stocks can supply some but no more than five days of food; about 8.7 million are in counties with five to ten days food from grain stocks, and so forth as shown in figure 7.

It has been assumed that private grain stocks owned by farmers can be obtained by the government for relief of potential starvation of large fractions of the U.S. population in a postattack situation. Some form of guarantee, possibly federal promissory notes, should be given by the government to assure the farmer of just compensation for his investment and labor and to allay his feelings of anxiety for his own future. Such a guarantee may be difficult to produce in a postattack situation unless it is evident to the farmer that the federal structure of government remains secure

and firmly in power. Federal authority will depend on the existence of a functional national leadership with the appearance of self-confidence and on the existence of a credible recovery program.

Shipment of Grain

The availability of grain in the United States being assured, the next problem to be considered is how to ship the grain. Will enough transportation and fuel survive, and how severely will destroyed bridges, debris, and fallout limit transportation?

The United States has the greatest transport capability of any nation on earth. In 1970, the total volume of intercity traffic amounted to almost two trillion ton-miles (figure 8) of which the railroads transported about 40%, oil pipelines about 22.5%, motor vehicles, 21.3%, inland waterways, 15.7%, and aircraft (not shown in figure 8) about 0.5%.

Volume of Domestic Intercity Traffic (from *Statistical Abstract of the United States 1972*).

Figure 8. Volume of domestic intercity traffic

The estimated number of privately and publicly owned transport units in the United States in 1974 and some previous years is listed in table 1. After a nuclear war, most of the transport capability of motor vehicles and aircraft will probably continue to exist as a result of dispersion and protective measures taken during the crisis period preceding the attack. However, oil pipelines will probably not be able to function at all for some weeks or months after the attack.

Railroad rolling stocks can be moved out of high-risk areas during the crisis period. Most of the major switchyards, warehouses, and repair facilities are located in major cities and would be either severely damaged or destroyed by the hypothetical attack. A previous study (Hamberg, p. 60) indicates that "in no case would rail traffic be completely blocked" by destruction of "rail activity centers," although circuitous routing would be required to get around the damaged facilities in many cases. The major restriction to rail shipments in the early postattack situation will be the destroyed bridges across major rivers such as the Mississippi, Missouri, Ohio, and Tennessee rivers. A few temporary railroad bridge construction sets may exist for military use, and railroad ferries exist at a few river locations, but these will probably not be adequate. Shipments of crucial supplies across rivers during the first few weeks or months after the attack may have to be accomplished by unloading boxcars at transfer points along the rivers, where the materials are then transported across the rivers by barges or by trucks on portable pontoon bridges.

The railroads are equipped to carry grain in large quantities, and loading and unloading equipment for grain in and out of box-cars exists throughout the grain-producing rural areas (Ladd and Lifferth). The lower cost and greater efficiency of rail movement at about 1.62¢ per ton-mile and 200 ton-miles per gallon of fuel (Hirst), as compared with 8.24¢ per ton-mile and 58 ton-miles per gallon for trucks (1973 prices), makes the railroads appear attractive for the major bulk of emergency shipments in the postattack situation. How-

ever, trucks will be essential for many rural pickups and deliveries.

There is a trend for truck terminals to be located along interstate highways outside of urban areas. Because of this trend and because of the mobility of the trucks, it is estimated that 60% to 80% of the current trucking capability would survive the hypothetical attack, providing that adequate measures are taken during the crisis period to provide protection during and after the attack.

In 1972, trucks consumed about 8.1 billion gallons of fuel in transporting 470 billion ton-miles of intercity freight at an average rate of 22.2 million gallons and 1,290 million ton-miles per day. This consumption amounted to about 8% of the total motor fuel (105 billion gallons) consumed for all highway traffic (Transportation Association of America). The average quantity of diesel fuel and distillate fuel oil stored in tanks in 1973 was about 5.67 billion gallons and the average quantity of gasoline was about 7.39 billion gallons (U.S. Dep. Interior). About 60% of these fuels will likely be destroyed in the hypothetical attack, which would leave about 2.27 billion gallons of diesel and distillate fuel oil and 2.96 billion gallons of gasoline surviving, if these numbers for 1973 are representative of the fuels in storage at the time of the attack. If this total of 5.23 billion gallons were to be used only by trucks in the postattack situation at the same average rate as before the attack, i.e., at 22.2 million gallons per day, this supply would last for 236 days, which is probably adequate to carry the nation through the survival stage into the recovery stage.

The problem of calculating the shipments of grain from surplus areas to deficit areas such that the total ton-miles of shipment is minimized is a typical problem of linear programming (Hillier and Lieberman). A detailed transshipment model for grain was developed by Ladd and Lifferth primarily to maximize joint net revenue of grain producers, which does not apply in a postattack situation. The development of a model to select shipment routes to minimize radiation exposure to transport workers is considered to be unnecessary for this program because within two weeks after the attack the radiation levels in nearly all areas of the country would decay to such an extent that train and truck operators could pass through the hottest areas without requiring medical attention. Elements of risk in transportation and in the availability of grain could be introduced into the calculations by various models, possibly by modifications of the risk models described by Hazell and Scandizzo. However, the additional complexities and expanded computer program development that would be required by these inclusions are considered to be beyond the scope of this project.

The particular problem at hand is solved with an unpublished program called TRANS-

PORT, developed by Holcombe and modified by Westley and Coleman. The initial solution was attempted with a data base that used counties as the cellular unit of data. When counties are used as the basic data cell, the requirements for solutions of the problem with the TRANSPORT program exceed the memory capability of our large computers; hence, the county information was consolidated into BEA's (business economic areas) as defined by the U.S. Department of Commerce. There are 171 BEA's in the coterminous United States, compared with about 3,300 county-type divisions.

A BEA is considered to be a source if 60% of the 1973 grain production in that BEA provides more than 365 days of food for the relocated ADAGIO population in that BEA, and shipments from a source are terminated when the reserve is depleted to the level of 365 food-days. Distances are computed along a great circle on the earth's surface connecting the geographical centroids of the BEA's.

The problem is to minimize the total ton-miles required to ship grain from BEA's that have a surplus to those that have a deficit. Let Z be total ton-miles, x_{ij} be tons shipped from BEA i to BEA j, d_{ij} be the distance from BEA i to BEA j, X_i be the initial quantity of grain in BEA i, R_i be the reserve quantity of grain stocks that must remain in BEA i after shipments are completed, and P_i be the number of people in BEA i. Then the problem may be stated as follows:

$$\min Z = \sum_i \sum_j d_{ij} x_{ij}$$

subject to

$$\sum_j x_{ij} < X_i - R_i \geq 0$$

and

$$\sum_j x_{ij} = R_j - X_j \geq 0.$$

For this particular problem, the population is assumed to be relocated according to the ADAGIO program as shown in figure 6. The initial grain stocks in each BEA are assumed to be 60% of the 1973 grain production. The grain on hand in BEA i is designated by G_i in pounds, and S represents the number of days of food reserve to be retained in the BEA's with surplus grain.

The parameter D is introduced to provide a time dependence in the program. D is defined as the number of days supply shipped to deficient BEA's. For simplicity, the shipments are assumed to be accomplished in a negligible time.

The grain reserve for grain-rich BEA's is specified by choosing S to be 365 days and by defining $R_i = 0.001P_iS$, based on a requirement of 0.001 tons of grain per person per day. Shipments are allowed from a BEA as long as $G_i > R_i$. For grain-poor BEA's, the amount of grain shipped to BEA j brings the reserve up to $R_j = 0.001P_jD$.

Two cases are considered. (*a*) Shipments are made for one week reserve at a time ($D = 7$) to each grain-poor BEA, and after each weekly shipment the amounts are added and subtracted to the appropriate BEA's, and a new optimum shipment is found for the subsequent week. (*b*) Shipments are made for multiples of a week reserve ($D = 7, 14, 21, \ldots$), and optimization of the shipments is made for the entire period in each case.

These two procedures result in identical solutions for the first six weeks. For the seventh week through the nineteenth week, the weekly shipments (case *a*) result in slightly greater values of cumulative ton-miles than case *b* (2.913 trillion ton-miles compared with 2.825 at nineteen weeks).

A solution of the grain shipment problem for the first six weeks is shown in table 2. The total shipments amount to about 91,000 tons the first week and increase to about 305,000 tons by the sixth week. As might be expected from an explanation of figures 5 and 6, the shipments specified by the solution to the linear program for the first week involve those BEA's that are people-rich but grain-poor, particularly parts of California, Florida, and New England states. The number of train carloads or truckloads or barges that are required to ship the grain if only one mode of transportation is used is also shown for each week in table 2. The number of train carloads (or truckloads) increases from 1,663 (or 5,078) in the first week to 5,785 (or 17,672) in the sixth week.

In comparison, the number of railroad carloads and truckloads per week in 1970, considering only those vehicles suitable for hauling grain, averaged about 266,000 and 308,000, respectively. The sixth-week grain shipments in table 2 require about 2% of the 1970 railroad capability or about 6% of the 1970 trucking capability if only one mode of transportation is used. Actually all three modes of transportation would be used to some extent, although the use of barges would probably be highly limited during the first few weeks because of the destruction to locks and port facilities and

[a] It is assumed that a closed or covered railroad car (adapted for emergency use) averages 55 tons per load and a closed truck averages 18 tons per load.
[b] No waterways connecting source and destination.

obstructions by fallen bridges. Barges are extremely useful in hauling bulk cargo such as grain, averaging about 1,100 tons per load, equivalent to about twenty average railroad carloads.

The heaviest shipments are from the Baltimore BEA, no. 17, to the New England BEA's, in which 26.44 million people are located according to the ADAGIO distribution. In the seventh week (not shown in table 2), the grain reserve in the Baltimore BEA is exhausted. Shipments to the New England BEA's must come from other more distant BEA's, such as Norfolk, Virginia.

The solution for the shipment problem beyond six weeks may be meaningless for two reasons. First, people may begin to move out of the relocation areas. Second, the Mississippi River may become open to barge traffic, unloading facilities for ships and barges along the Atlantic Coast may begin to operate, and grain shipments from the grain belt may become feasible. A complete solution of the grain shipment problem, involving costs of each mode of transportation and actual distances of travel, is infeasible because the precise location and degree of damage to facilities and the limitations imposed by fallout, debris, and damaged bridges are unpredictable.

The solution of the grain shipment problem indicates that, within the assumptions described earlier, grain can be shipped to alleviate food shortages well within the capabilities of the surviving transportation facilities and petroleum after a large nuclear attack. Limitations and restrictions imposed by radiological hazards from fallout and disruption of communications and electrical power are discussed in greater detail in a report by Haaland, Chester, and Wigner.

Intersector-Distributional Implications of Agricultural Technical Progress in an Open Economy: An Extension

Dũng Nguyen

In a recent paper, Akino and Hayami (A–H) present a method to estimate the social benefits due to rice breeding research in the recent experience of Japan's economy.[1] In addition to the estimation of the social rate of returns to public investment in rice research, the authors quantify the distribution of social benefits between consumers and producers based on conventional concepts of consumer's surplus and producer's surplus. In a static demand-supply framework, the authors specify the autarky and the open economy as two polar cases within which reality lies. In another paper with Herdt, Hayami formulates a similar model to account for the distributional impact of technological change in subsistence agriculture, where the Philippines is used as an example. In a sense, the Hayami and Herdt (H-H) model is both an extension and a reduction of the A-H model. For present purposes, the following comparisons between the two papers are particularly relevant.

(*a*) In the H-H paper, three types of income distribution are discussed: intersectoral distribution (producers versus consumers), distribution among producers (small versus large farmers), and distribution among consumers (low- versus high-income class). On the other hand, only the first is examined in the A-H paper.

(*b*) The effect of the government's price control policy is not considered in the H-H model, whereas it is seen as one of two polar cases in the context of the open economy in the A-H model.

(*c*) However, the A-H analysis is extended in the H-H paper by taking into consideration the effect of the ratio of marketable surplus to total output (which may be conveniently termed as the agricultural commercialization rate) on the intersectoral distribution of economic gains.

With respect to (*a*), the present note is concerned only with the first type of income distribution. The extension made by Hayami and Herdt mentioned in (*c*) seems to be quite relevant in today's developing economies, where agriculture may be the more important sector. Furthermore, it may well be speculated that the impact of commercialization rate should be taken into account in analyzing the distribution of gains from rice breeding research in Japan during the period covered by the A-H study (1915–61).

With regard to (*b*), it seems that, by merely identifying the two polar cases, the A-H model would not give specific values for consumer's and producer's gains as the result of a rightward shift in the supply schedule due to rice breeding techniques.[2] Similarly, complete disregard of the price control policy's constraint in the H-H paper would lead to unwarranted interpretations pertaining to intersectoral distribution.

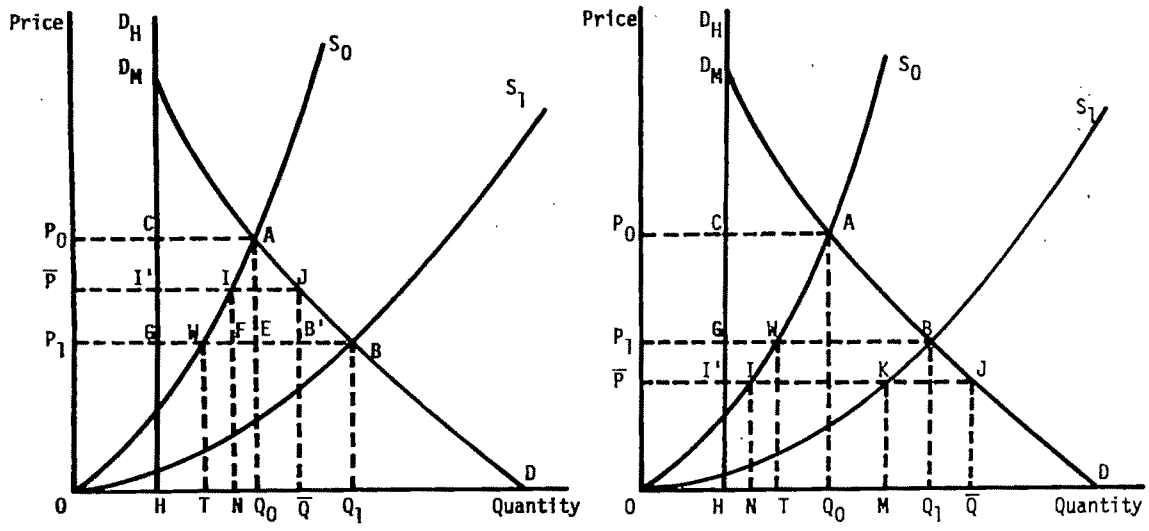
This note is mainly concerned with the issues mentioned in the preceding paragraph. I attempt to extend the above two models to take into account the case of open economy, where it is assumed that the market price is subject to a controlled ceiling price at which the government has to import a certain amount of agricultural produce in order to meet domestic demand.

To conserve space, the reader is referred to the H-H paper for notations and definitions.

The Extended Model

Let us introduce a new variable into the H-H model, namely, ceiling price, which is shown in the graph as $O\bar{P}$. The H-H analysis would not be affected if $O\bar{P} > OP_0$, i.e., if the equilibrium price before technological change is lower than the ceiling price. However, this is clearly not an interesting case in my framework. Thus, the two general cases considered are $OP_0 \geq O\bar{P} \geq OP_1$ and $0 < O\bar{P} \leq OP_1$. For convenience, they are referred to as the first and second general case, respectively, throughout this note.

The First General Case



The first general case may be depicted in figure 1.A. With the ceiling price $O\bar{P}$, the quantity demanded is shown as $O\bar{Q} = \bar{P}J$, and the domestic quantity

Dũng Nguyen is a doctoral candidate at the University of Maryland.

For their encouragement and helpful comments, the author wishes to thank Randolph Barker, Bryan Boulier, Christopher Clague, Mahar Mangahas, and a reviewer of this *Journal*.

[1] A slightly different version of their paper appears as chapter 6 in Hayami.

[2] In other words, the A-H analysis can only estimate a range of values. Any conclusion drawn from it concerning the distributional impact seems to be uncertain. More importantly, it is shown below that the reality may not even lie within the two polar cases as stated by Akino and Hayami.

A. The First General Case

B. The Second General Case

Figure 1. The impact of technological change

supplied is indicated by $ON = \bar{P}I$. Under normal circumstances, price tends to move upward to the equilibrium point at A. However, with the policy of price control, the quantity demanded is satisfied by import of the crop in question. Quantity imported can be represented by IJ in figure 1.A. Then, due to technological change, a new equilibrium position is established at B with OP_1 and OQ_1 as the new equilibrium price and quantity, respectively. We have change in consumer's surplus: area $JI'GB$, change in producer's revenue: area $BFNQ_1$ − area $H'GF$, and change in cost of production: area BOQ_1 − area ION. Obviously, the effects of the rate r on the change in consumer's surplus and producer's revenue are generally the same between the H-H model and the first general case. Nevertheless, it is equally obvious that the levels of change in consumer's surplus and producer's revenue are generally different.

From figure 1.A, if $O\bar{P} = OP_0$, my first general case becomes the H-H model. At another extreme, if $O\bar{P} = OP_1$, area $JI'GB$ becomes line GB, i.e., there is no change in consumer's surplus. The change in producer's revenue can now be indicated by area $BWTQ_1$, which is clearly independent of the agricultural commercialization rate r.

The mathematical version of the preceding discussion can be seen by first approximating the following relationships:

(1) $\bar{p} = p_0\left(1 - \dfrac{m}{b+n}\right)$ and

$$\bar{q} = q_0\left(1 + \frac{nm}{b+n}\right);$$

and

(2) $p_1 = \bar{p} - p_0\left(\dfrac{k-m}{b+n}\right)$ and

$$q_1 = \bar{q} + q_0\frac{n(k-m)}{b+n},$$

where m denotes the percentage shift in supply due to import such that demand for the crop is satisfied, and variables with bars indicate the controlled market price and quantity. The following approximations are obtained:

(3) Change in consumer's surplus

$$= \bar{p}\bar{q}\,\frac{(k-m)r}{b+n-m},$$

(4) Change in producer's revenue

$$= \bar{p}\bar{q}\left[\frac{(k-m)(n-r)}{b+n-m} + \frac{m}{1+m}\right],$$

(5) Change in cost of production

$$= \bar{p}\bar{q}\,\frac{b[m(b+n)+(k-m)(n-1)]}{(1+b)(b+n-m)(1+m)},$$

and

(6) Change in producer's surplus

$$= \bar{p}\bar{q}\,[(k-m)[(1+m)(1+b)(n-r) - b(n-1)] + m(b+n-m)]\,[(1+b)(b+n-m)(1+m)]^{-1}.$$

Equations (3) to (6) indicate the effects of the commercialization rate on producer's and consumer's gains. Generally, its effects are in the same direction with those discussed in the H-H paper, although the levels of effect are clearly different.

Only when $m = 0$ do equations (3) to (6) give identical results with those from the H-H model. Moreover, if it is assumed that $r = 1$, then the H-H model (or the first general case with $m = 0$) essentially reduces to the A-H autarky situation. In other words,[3]

(7) Change in consumer's surplus $= \bar{p}\bar{q}\,\frac{k}{b+n}$,

(8) Change in producer's surplus

$$= \bar{p}\bar{q}\,\frac{k(n-1)}{(1+b)(b+n)},$$

(9) Change in total social benefit $= \bar{p}\bar{q}\,\frac{k}{1+b}$.

When $k = m$, the first general case describes another extreme situation that would imply self-sufficiency in subsistence crop under consideration. Equations (3) to (6) now become

(10) Change in consumer's surplus $= 0$,

(11) Change in producer's revenue

$$= \bar{p}\bar{q}\frac{m}{1+m} = \bar{p}\bar{q}\,\frac{k}{1+k},$$

(12) Change in cost of production

$$= \bar{p}\bar{q}\frac{mb(b+n)}{(1+b)(b+n-m)(1+m)}$$

$$= \bar{p}\bar{q}\frac{kb(b+n)}{(1+b)(b+n-m)(1+m)},$$

and

(13) Change in producer's surplus

$$= \bar{p}\bar{q}\frac{m}{(1+b)(1+m)} = \bar{p}\bar{q}\,\frac{k}{(1+b)(1+k)}.$$

Thus, the picture is changed. While producers enjoy an increase in income, there seems to be no change at all in the consumer's gain due to technical progress. Another point worth noting is that the commercialization rate r is no longer present in the above equations, i.e., changes in producer's and consumer's gains are clearly independent of the rate r. This case, of course, invalidates some of Hayami and Herdt's conclusions regarding the effects of the rate r. Besides, this situation describes another polar case discussed in the A-H paper, namely, the open economy case.

The Second General Case

Figure 1.B illustrates the second general case where the equilibrium price after technological change is higher than or equal to the ceiling price. Since technological change does not affect the market price, which is the controlled price, there is no change in consumer's surplus. Change in producer's revenue, however, is positive and independent of the commercialization rate as this change can be represented by area *KINM* in figure 1.B. Finally, corresponding change in cost of production is indicated as area *KOM* − area *ION*.

The following equations approximate relevant areas shown in figure 1.B:[4]

(14) Change in consumer's surplus $= 0$,

(15) Change in producer's revenue $= \bar{p}\bar{q}\frac{k}{1+m}$,

(16) Change in cost of production

$$= \bar{p}\bar{q}\frac{kb(b+n)}{(1+b)(b+n-m)(1+m)},$$

and

(17) Change in producer's surplus

$$= \bar{p}\bar{q}\frac{k}{(1+b)(1+m)}.$$

Here is another interesting case that is usually observed in some developing countries where technological progress, although remarkable, cannot increase production level up to the point where total import of a particular subsistence crop is completely substituted. This appears to be the case of the Japanese economy as described by Akino and Hayami: "In reality, in spite of the efforts to shift the rice production function upwards, domestic supply could not keep up with the expansion in demand, resulting in rice imports in the order of 5% to 20% of domestic production" (p. 4).[5]

Thus, this discussion seems to indicate that the reality of the Japanese agricultural situation may be represented by the second general case. On the contrary, the Akino and Hayami autarky and open economy cases are two extremes of the first general case. It should be obvious, therefore, that the reality may not even lie within the polar cases as asserted by Akino and Hayami. The difference between the first and the second general case can be clearly seen. Only when $OP_1 = O\bar{P}$ should the two general cases be identical. In other words, if $k = m$, equations (14) to (17) give consistent results with those in equations (10) to (13).

Table 1 shows the results of the reestimation of the distribution of gains based on formulae of the extended model. Specific formulae used are indi-

[3] These results can be, of course, derived directly from the Hayami and Herdt model. I verify below that these would give very close approximations with those in the Akino and Hayami paper (see table 1). The slightly different notion of rate k in the Akino and Hayami paper may be noted, where k is defined with reference to the quantity supplied after but not before technological change.

[4] I have greatly benefited from the comments of the reviewer who pointed out some errors in a previous formulation.

[5] Unfortunately, they state, "However, this does not require modification of our model" (p. 4).

Source: Akino and Hayami.

[a] Figures appearing in parentheses are obtained by using the formulae of the extended model, equations (8) and (9) in text and total social benefit of the open economy case $= \bar{p}\bar{q}\,\frac{k}{(1+b)(1+k)}$. The value of $\bar{p}\bar{q}$ is derived by taking the consumer's gain computed in the Akino and Hayami paper as "given" through equation (7). Furthermore, the values of total social benefit computed from the extended model for the autarky case (column (3) in parentheses) are equal to those computed in the Akino and Hayami open economy case (column (4) not in parentheses). This is by no means a coincidence. The reason is that Akino and Hayami approximate change in total social benefit in open economy case by the formula (their notation) $kp_0q_0 = p_0q_0h/(1+\gamma)$, or, in my notation, $\bar{p}\bar{q}k/(1+b)$, which is exactly change in total social benefit according to the extended model's version of the autarky case (see equation (9)).

[b] By using the formula: change in total social benefit = change in producer's surplus $= \bar{p}\bar{q}k/(1+b)(1+m)$.

cated in the notes below the table. Two alternative values of m are used, 5% and 20%, representing the possible range of import rates as suggested by Akino and Hayami. Given the specific value of m, the generalized formulae would give approximations for the "real" levels of producer's gains, based on which certain conclusions about income distribution can then be made.

In summary, the Akino and Hayami autarky case, the Akino and Hayami open economy case, as well as the Hayami and Herdt model, are only special cases of the extended model being developed so far. When $m = 0$, the extended model reduces to that of Hayami and Herdt. For $m = 0$ and $r = 1$, the results of the Akino and Hayami autarky case are obtained. Finally, if $k = m$ and $r = 1$, one can then arrive at the results of the Akino and Hayami open economy case.

Concluding Remarks

At the beginning of the paper, I argued that the Akino and Hayami analysis cannot give any specific conclusions regarding the intersectoral distribution of economic gains due to agricultural technological progress. Their analysis can only identify two polar situations, and it suggests that the reality of the Japanese experience lies somewhere in between. My extended model, on the other hand, offers a method to specify the distribution pattern once the ratio of import to total output is known. I also demonstrate that the reality of the Japanese agricultural situation may not even lie within the two polar cases as Akino and Hayami assert.

Besides, it seems that effects of the agricultural commercialization rate must also be taken into consideration in the manner suggested by Hayami and Herdt if a closer estimation of the distribution of economic gains is to be expected.

With respect to the Hayami and Herdt model, the conclusion of their paper states that "modern technology, such as the high-yielding rice varieties, benefits both consumers and producers. Within agriculture, it has an effect of promoting a more equal income distribution through downward pressure on prices. . . ."

However, it is shown in my extended model that this conclusion may not be generally valid. For a country that has to import a certain subsistence crop, the rightward shift of the supply schedule due to technological change tends to substitute the import partially or fully; thus, the price level may not be reduced at all. Under these circumstances, as indicated in this analysis, only producers are better off, while consumers are neither better nor worse off. Meanwhile, the agricultural commercialization rate may not have any effect as shown by the absence of the variable r in the respective equations.

On the other hand, if the value of k exceeds that of m, then the conclusions reached by Hayami and Herdt concerning the effects of the rate r are found to be consistent with those from the extended model. However, the level of impact of technological change (variable k) and of the commercialization rate r in the Hayami and Herdt model is different from that in the extended model.

This difference can be clearly seen by comparing Hayami and Herdt's calculation with the values obtained from generalized formulae where various levels of m are assumed (0, 5%, 10%, and 15%). This is done in table 2, where the Philippines is used as an empirical illustration with $k = 10\%$, $r = 0.40$, $n = 0.30$, and $b = 0.30$.

Table 2. Distribution of Gains in Economic Welfare Due to Technical Progress in Rice Production Between Producers and Consumers in the Philippines, 1967/70–1971/72 Averages

	Welfare Gains in Money Terms (Million Pesos)[a]			
	$m = 0$[b]	$m = 5\%$	$m = 10\%$	$m = 15\%$
Consumers	146 (87%)[c]	73 (45%)	0 (0)	0 (0)
Producers	22 (13%)	90 (55%)	153 (100%)	147 (100%)
Total	168	163	153	147

Source: Hayami and Herdt.

[a] The computation is based on the given information: $k = 10\%$, $r = 0.40$, $n = 0.30$, $b = 0.30$, and $pq = 21.90$ million pesos.

[b] Hayami and Herdt's results.

[c] Welfare gains in percentage terms are expressed in parentheses.

Table 2 shows that the distribution pattern of gains varies tremendously with different values of m. Thus, the above-cited conclusion by Hayami and Herdt, who disregard the variable m in their model, may not be valid. Lastly, since I am concerned only with the question of equity, the paper ignores the social gains in terms of foreign exchange due to technological advances in agriculture.

Benefit-Cost Analysis of Surfaced Roads in the Eastern Rice Region of India

John Spriggs

In a recent study, Easter, Abel, and Norton attempted to measure the contribution of various inputs to total output in the eastern rice region (ERR) of India.[1] They included both the traditional inputs such as land, labor, and fertilizer as well as nontraditional inputs such as irrigation, technology, environmental factors, and infrastructure. They estimated production functions in log form using district level data and found that the production elasticity on surfaced roads was highly significant and very stable under alternative equation specifications. The present research note uses their estimated production elasticity on surfaced roads (0.208) in estimating a benefit-cost measure of public investment in surfaced roads in the ERR. In this paper, a model is set up to estimate the benefits, then costs are estimated, and, finally, the estimated benefits and costs are joined together in a benefit-cost ratio.

According to the Easter-Abel-Norton (EAN) study: "Surfaced roads appear to be important in explaining productivity differences among districts. . . . The absence of roads in a heavy rainfall area such as the rice region has the effect of raising input prices paid by farmers and lowering output prices received by them due to higher transportation costs." Following this, the benefits of public investment in surfaced roads may be assessed as follows. Consider figure 1, which depicts the basic economic interrelationships between the rural producing and consuming sector, the marketing sector, and the nonrural consuming sector. Figure 1(a) describes the supply (S) and demand (D) curves for the rural or food surplus area. Figure 1(b) describes the excess supply (ES) curve from this area and a demand (DU) curve for the urban or food deficit area. Figure 1(c) describes the supply (SM) and demand (DM) curves for marketing services, where the supply of marketing services are assumed to be perfectly elastic over the observed range of services supplied. This is thought to be reasonable, in the absence of congestion costs, following some earlier research (for example, Ruttan).[2] Using a perfectly competitive model, the last mentioned curve is a vertical subtraction of the ES from the DU curve. Equilibrium prices at the farm level (PF_1) and wholesale level (PR_1) and the equilibrium quantity flowing through the system (Ox_1) are determined by the intersection of the DM and SM curves in figure 1(c). Total quantity supplied by the rural sector is OX_1.

The effect of increasing surfaced roads is to lower both the prices of purchased inputs to the rural producer and the costs of transporting the product to the food deficit area. These effects manifest themselves in downward shifts in the S and SM curves, respectively.

Ideally, direct measures of these shifts are desired to determine a unique solution to the gain in economic surplus, but these are not known. However, we do have an estimate of the effect of increasing surfaced roads on crop output from the EAN study.[3] Using this information, solutions can be obtained that encompass a broad range of possible solutions. Three such solutions are obtained here, coinciding with the following possible situations.

(a) The SM curve shifts, but the S curve does not. This assumes the investment in more surfaced

John Spriggs is a research assistant in the Department of Agricultural and Applied Economics, University of Minnesota.

University of Minnesota Agricultural Experiment Station, Miscellaneous Journal Series Paper No. 1636. The author wishes to thank Martin Abel, William Easter, Willis Peterson, Terry Roe, Peter Warr, and Ian Wills for their helpful comments. The author is responsible for any remaining errors.

[1] The ERR as defined by Easter and Abel contains sixty-nine districts in the states of Andhra Pradesh, Bihar, Madhya Pradesh, Maharashtra, Orissa, Uttar Pradesh, and West Bengal.

[2] One may still argue that the type of marketing services required as a result of more surfaced roads may differ from the type envisaged by Ruttan. For example, storage facilities may become more specialized, and the method of transportation may be more capital intensive. These would tend to imply an upward sloping long-run supply curve for marketing services.

[3] EAN's production elasticity on surfaced roads probably underestimates the true effect of increasing surfaced roads on crop output. Consider their production function: $Q = f(I, SR, Z)$, where Q is crop output, I is conventional inputs, such as fertilizer, SR is length of surfaced roads, and Z is other explanatory variables. The function is estimated assuming I and SR are independent variables, but in fact surfaced roads increase crop output in part via an increase in the use of the I inputs. Hence dI/dSR is not zero and is very likely positive. The true effect of increasing surfaced roads on crop output is given by dQ/dSR, where $dQ/dSR = \frac{\partial Q}{\partial I}\frac{dI}{dSR} + \frac{\partial Q}{\partial SR}$. Using instead the production elasticity or $\partial Q/\partial SR$ results in a bias of $\frac{\partial Q}{\partial I}\frac{dI}{dSR}$. In the relevant regression of the EAN study (table 4, regression 8), $\partial Q/\partial I$ is found to be positive for all inputs except labor. But labor is insignificant with a t-value of 0.523. Thus, $\frac{\partial Q}{\partial I}\frac{dI}{dSR}$ is very likely positive and $\partial Q/\partial SR$ underestimates dQ/dSR. The result is that benefits are underestimated, and any benefit-cost ratios will tend to be more conservative than otherwise.

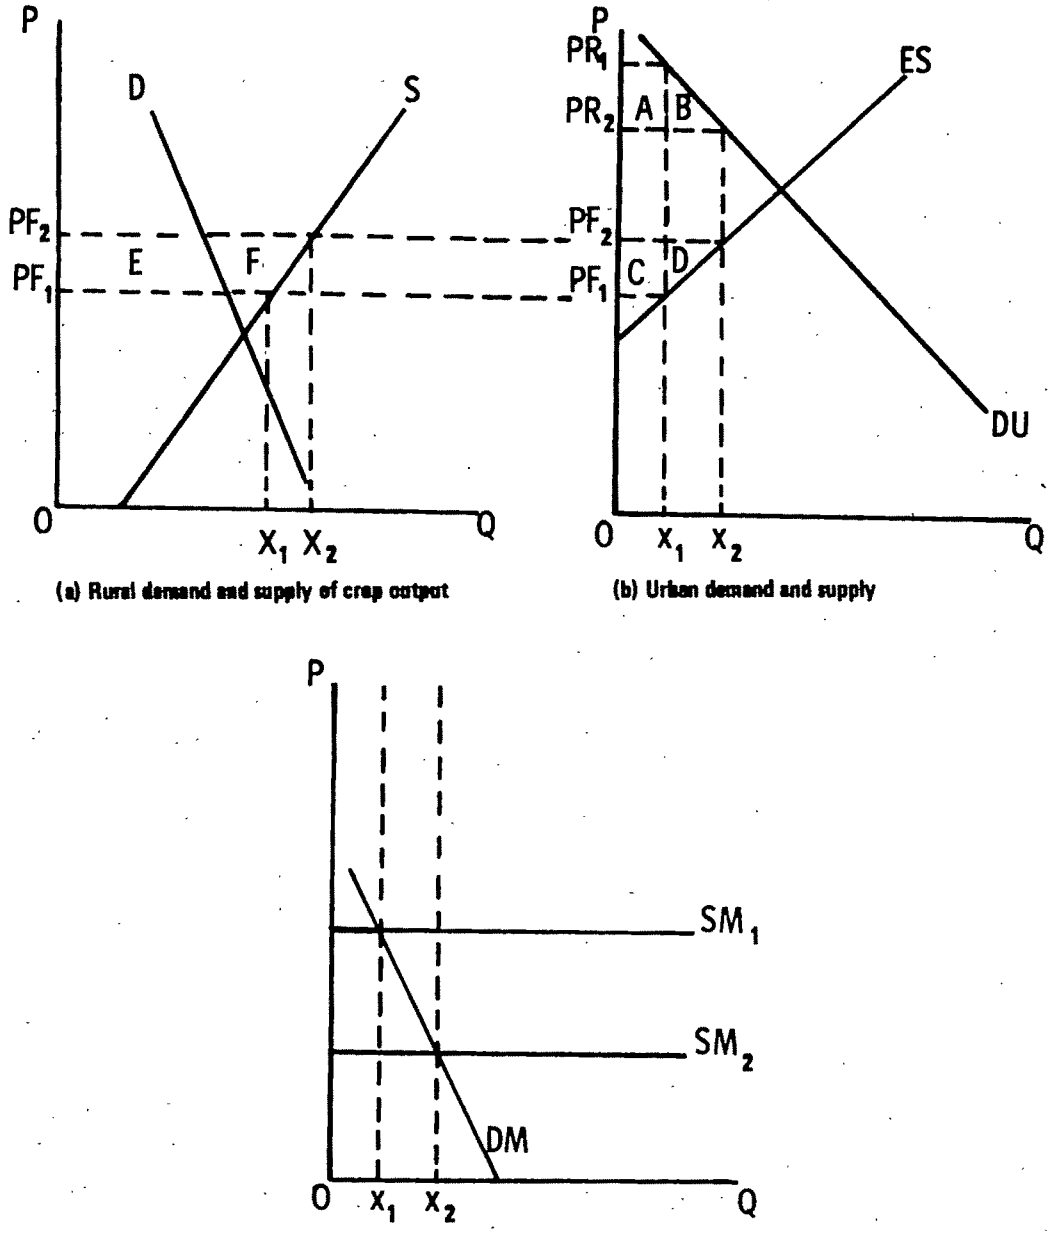

Figure 1. Gain in economic surplus when it is assumed marketing costs are reduced but input prices are constant

roads decreases marketing costs but does not affect input prices. As a result, product price decreases in the urban sector and increases in the rural sector.

(*b*) The *S* curve shifts, but the *SM* curve does not. This assumes that more roads decrease input prices but have no effect on marketing costs. As a result, product price in both the rural and urban sectors will decline.

(*c*) Both the *S* and *SM* curves shift so as to leave farm price unchanged. This assumes that more roads decrease both input prices and marketing costs. As a result, the farm price of output does not change but the urban price decreases.

As shall be seen, these three situations yield, respectively, a high, low, and intermediate estimate of the benefits derived from building more surfaced roads in the ERR.

Consider in some detail the method of solving for the gain in economic surplus under assumption (*a*). A 1% increase in surfaced roads that leads to an

increase in rice output of $(n \times 100)\%$ is postulated. In figure 1, this is represented by the increase from X_1 to X_2. Thus, $n = (X_2 - X_1)/X_1$. While the end result of more roads is greater output, this is assumed to occur only because the increase in roads has reduced the cost of transferring products from the farm to the nonrural consumer. Therefore, the supply of marketing services curve shifts from SM_1 to SM_2. Price paid by the urban consumer falls from PR_1 to PR_2, while the price to producers and rural consumers rises from PF_1 to PF_2. In figure 1(a), rural consumers lose area E in consumer surplus, while producers gain area $E + F$ in producer surplus. Thus, the rural population has a net gain in economic surplus of area F, which is equivalent to area $C + D$ in figure 1(b). Urban consumers gain area $A + B$ in consumer surplus in figure 1(b).

Annual net gain in economic surplus (ANG) = area $(A + B + C + D) = 1/2(x_1 + x_2)[(PR_1 - PR_2) + (PF_2 - PF_1)]$. Using the relation, $n = (X_2 - X_1)/X_1$, and the approximate elasticity relations: elasticity of urban demand = $E(DU) \simeq -[(x_2 - x_1)/x_1]/[(PR_1 - PR_2)/PR_1]$; elasticity of rural supply = $E(S) \simeq [(X_2 - X_1)/X_1]/[(PF_2 - PF_1)/PF_1]$; and elasticity of excess supply = $E(ES) \simeq [(x_2 - x_1)/x_1]/[(PF_2 - PF_1)/PF_1]$; we obtain $(x_1 + x_2) = x_1 + x_1(1 + n[E(ES)/E(S)])$, $(PR_1 - PR_2) = -PR_1 n\, E(ES)/[E(DU)E(S)]$, and $(PF_2 - PF_1) = (nPF_1)/E(S)$. Thus, we obtain ANG $= [x_1 n/2E(S)]\,[(2 + n\, E(ES)/E(S))(PF_1 - PR_1 E(ES)/E(DU)]$.

To determine a value for ANG, values are assigned to x_1, n, $E(S)$, $E(DU)$, $E(ES)$, PR_1, and PF_1 as follows.

(*a*) The initial quantity of rice marketed in the ERR (x_1) was determined as

$$x_1 = \sum_{i=1}^{6} [(\textit{rice output})_i \times (\textit{percentage marketed})_i],$$

where $i = 1, \ldots, 6$ are the states of Andhra Pradesh, Bihar, Madhya Pradesh, Orissa, Uttar Pradesh, and West Bengal.[4] "Rice output" data are for those states or parts of states included in the ERR. "Percentage marketed" data are at the state level only. The values for rice output, percentage marketed, and, hence, x_1 were calculated for the marketing years 1967–68 and 1968–69, and a simple average over the two years was used. Thus, $x_1 =$ 37,230,000 quintals (India, Government of, 1972a, b; 1967–68; 1968–69).

(*b*) For the percentage increase in rice output resulting from a 1% increase in surfaced roads (n) is used the coefficient on surfaced roads obtained in the EAN study, table 4, regression 8. Its value is 0.208.[5]

(*c*) The value of the price elasticity of rice supply ($E(S)$) is an estimate obtained in a study using Punjab data for the period 1914–45 (Krishna). $E(S) =$ 0.59.[6]

(*d*) The value of the price elasticity of demand facing nonrural consumers ($E(DU)$) is an estimate obtained from a recent study using all-India data for the period 1951–68 (Pandey). Thus, $E(DU) = -0.75$.

(*e*) To obtain the value for the initial price facing nonrural consumers (PR_1), the following process was used. For each of the six states in the ERR, data were obtained on the annual average wholesale prices of rice at selected markets in 1968 and 1969. The number of markets varied between states from three to six depending on the availability of data. Those in which prices were fixed by the government were omitted. For each state a simple average price was determined over the relevant markets and over the two years. The six simple average prices were weighted by the quantity of rice marketed in each state (or part of state) to obtain PR_1. Thus, $PR_1 =$ 113 rupees (Rs) per quintal (India, Government of, 1972b).

(*f*) Let the initial price received by producers (PF_1) equal $PR_1 - M_1$, where M_1 is the marketing margin when x_1 is marketed. No data could be found on the size of M_1. It was arbitrarily decided to assume $M_1 = 0.1\, PR_1$ and to use the resulting value of PF_1. As it turns out, the solution was not very sensitive to the size of the marketing margin. For example, when the marketing margin was doubled, the gain in economic surplus declined by only about 5%.[7]

(*g*) The price elasticity of excess supply ($E(ES)$) is given by $E(ES) = E(S)\, X_1/x_1 - E(D)\,(X_1 - x_1)/x_1$, where the values for $E(S)$ and x_1 have already been determined. The value of $E(D)$, the elasticity of rural demand, is assumed to be equal to $E(DU)$ PF_1/PR_1 or 0.68; and X_1, the initial quantity of rice produced in the ERR, is determined as follows. Rice output in the ERR was calculated for each of the marketing years 1967–68 and 1968–69, and a simple average over the two years was used. Thus, $X_1 =$ 207,970,000 quintals (India, Government of, 1972b, 1967–68, 1968–69). The value of $E(ES) =$ 6.4.

Using the values obtained in parts (*a*) through (*g*) above, the annual net gain in economic surplus was found to be Rs 141 million, of which about 91% was distributed in the urban consuming sector.

---

[4] The district of Bhandara (Maharashtra) is included with Madhya Pradesh.

[5] The dependent variable in the EAN study is the total crop output of which rice is the major crop. In this note, "the dependent variable" is simply rice output. The implications are as follows. If in fact all crops increase in output by about the same percentage, then the benefits will be underestimated by ignoring those benefits accruing to the nonrice crops. If in fact only rice increases in output, while other crop outputs remain the same or decline, then the benefits will be underestimated because the roads coefficient in the EAN study will be lower than if "rice output" were the dependent variable. The converse holds if other crop outputs increase while rice output does not.

[6] While the elasticity may be suspect since it neither pertains to the same region nor similar time period considered here, the benefits are not overly sensitive to changes in this elasticity. A 10% increase in this elasticity leads to a reduction in ANG of 4% under the first assumption, an increase of 4% under the second assumption, and a negligible change under the third assumption.

[7] Under the second and third assumptions, a 10% reduction in PF_1 will reduce ANG in economic surplus by 4% in each case.

Table 1. Benefits, Costs, and Benefit-Cost Ratios of Increasing Surfaced Roads by 1% in the ERR

	Benefits	Costs		*B/C* Ratio
		Development	Annual	
	———Million Ruppees, 1969 Prices———			
SM curve shifts, *S* curve does not	141	57.8	2.0	10.4
S curve shifts, *SM* curve does not	91	57.8	2.0	6.7
Both *SM* and *S* curves shift	108	57.8	2.0	8.0

Before considering the costs, turn briefly to the estimation of benefits under the two alternative assumptions. The methods of solution are not detailed, as they are of the same geometrical variety that was used above. Under these assumptions in which the *S* curve shifts, the shifts are assumed to be in a parallel fashion. Under the second assumption, where only the *S* curve shifts, annual net gain in economic surplus was found to be Rs 91 million, of which about 88% was distributed in the rural sector. Under the third assumption, where both the *S* and *SM* curves shift in such a way as to leave *PF* unchanged, the annual net gain in economic surplus was found to be Rs 108 million, of which about 60% was distributed to the urban consuming sector.[8]

With regard to the costs of a 1% increase in surfaced roads in the ERR, development cost and maintenance cost are considered. To obtain estimates of these costs, annual data (1959–69) were obtained on an all-India basis for the length of extramunicipal surfaced roads maintained by Public Works Department and Local Bodies and for the development and maintenance costs of state roads (deflated by the wholesale price index for India, all commodities) (India, Government of, 1971).[9]

A value for development cost was obtained by summing the deflated annual development costs over the ten-year period and dividing by the difference in road length between 1959 and 1969. The average development cost determined in this way is Rs 56,700 per kilometer (1969 prices). A value for maintenance cost was obtained by dividing the deflated annual maintenance cost by road length each year, 1959–69, and then averaging the results. The average maintenance cost determined in this way is Rs 1,970 per kilometer-year (1969 prices).

It may be argued that since these costs are drawn from all-India data they may not accurately reflect the cost of constructing or maintaining roads in the ERR because the higher than average rainfall in this region results in road costs above the national average. Moreover, bridge costs are ignored. Therefore, the cost figures arrived at above are doubled, and these adjusted costs are used in the following analysis.

The total length of extra-municipal surfaced roads in the ERR in 1969 (maintained by the Public Works Department) was about 51,000 kilometers. To increase road length by 1% (or 510 kilometers) involves a development cost of Rs 57.8 million (1969) and an annual maintenance cost of Rs 2.0 million (1969) (India, Government of, 1971; West Bengal, Government of).

To obtain a benefit-cost measure, assumptions about the flow of costs and benefits need to be added. Assume that the new roads are constructed within a year and the full benefits and maintenance costs accrue for each of the following ten years. After this time, the roads are scrapped with a zero salvage value. With regard to the rate of discount, since the major part of costs occur at the start, while the benefits are spread out evenly over ten years, the higher the discount rate, the lower is the benefit-cost ratio. By choosing a discount rate on the "high" side, say, 15%, any error will be on the side that tends to lower the ratio of benefits to costs. Allowing a 15% rate of discount, the resulting benefit-cost ratios under the three alternative assumptions are summarized in table 1.[10] The benefits and costs are also included for reference.

The results indicate that benefits relative to costs are substantial and, hence, that a lack of surfaced roads in the eastern rice region of India is likely an important constraint to development there. The Easter, Abel, and Norton study isolates the effect of surfaced roads as a regression coefficient. The present research note attempts to translate their result into a benefit-cost ratio. Although the calculations lack precision because of the sparsity of information, any error will tend to be on the side that will lower the ratio of benefits to costs. Despite this, the results indicate that increasing surfaced road density in the eastern rice region has a high payoff.

[*Received April 1976; revision accepted October 1976.*]

[8] While parallel shifts in the S curve are assumed under both the second and third assumptions, an alternative assumption of proportional shifts has a substantial effect on ANG in economic surplus. Recalculating the gains under this alternative assumption yields the values of Rs 51.6 million and Rs 86.6 million, respectively.

[9] State roads includes extramunicipal surfaced roads maintained by Public Works Department and Local Bodies. However, unsurfaced roads are also included in state roads. Hence, to this extent, the costs obtained in this note are probably biased upward.

[10] In the second and third cases, if the *S* curve is assumed to shift in a proportional rather than a parallel way, the *B/C* ratios are then 3.8 and 6.4, respectively.

Land Values and Allotment Rents

J. B. Bullock, W. L. Nieuwoudt, and E. C. Pasour, Jr.

The concept of economic rent is frequently used in analyzing the effects of price supports for crops produced under allotment programs. An allotment is an example of a resource that has no alternative use and is perfectly inelastic in supply. Allotments are fully utilized and, hence, acquire economic value as long as the return to the resources required in allotted crops is greater than from alternative enterprises. From an industry standpoint, these annual returns to allotments are economic rents in the classic sense.[1]

In practice, output is often restricted through the use of the land input (e.g., peanut allotments). When the output of a product is restricted through a land or acreage allotment, the annual rent to the allotment is capitalized into the price of land. It is common practice by economists to refer to these "quasi rents" to land (and other factors not perfectly elastic in supply) as economic rent.[2] Economic rent, as used throughout the remainder of this paper, is defined as the difference between the total payment to the resource and the opportunity cost of a resource not perfectly elastic in supply. The resource being discussed is land to which allotments are attached.

Since the value of rents accruing to acreage allotment rights become capitalized into land values (assuming that allotment is the only input perfectly inelastic in supply), the primary beneficiaries of such programs are the landowners at the time the program is implemented. If at a later date the allotment program is eliminated, land values again are altered. In most cases, land values decline *ceteris paribus*. This paper demonstrates, however, that the change in land value (and, hence, wealth) is seldom equal to the capitalized value of the allotment rents.

Most analyses of the effects of government programs on land prices assume that land is of uniform quality or productivity. Such analyses mask the differential effect of price support and allotment programs on land values for land of differing levels of productivity. In reality, allotment values for a given crop are observed to vary widely between production areas within states and between states.[3]

The purpose of this paper is to examine the effects on land values of abolishing an allotment program and to show why the effect is likely to be different for land in different production areas, depending upon the productivity and alternative uses of land in producing the allotted crop. The relationship between the elasticity of supply and land rent for homogeneous land is first investigated. After demonstrating the hypothetical relationship between land rent and allotment rent, the results of a recent empirical study of peanut allotment values are shown to be consistent with the theory developed.

Identification of Land Rent and Allotment Rent

The market for land used in the production of the allotted crop is illustrated in figure 1. The supply (opportunity cost) of land to be used for this crop is represented by SS,[4] while D_1 is the demand for land by producers of this crop if no price support or acreage restriction program is in effect, and Q_e is the amount of land that would be used to produce the crop if no price support or acreage restrictions are in effect. The existence of a product price support above the free market level shifts the demand for land to D_2, since the output from each acre is more valuable while production costs do not change. The acreage allotment imposed as a part of the price-support program is Q_a.

The price-support, acreage-restriction program generates annual payments to land of $\$P_s Q_a$. However, the opportunity cost of this land is only the area F. The marginal opportunity cost of land used by the allotment (Q_a acres of land) is P_o. Thus, landowners receive annual land rents equal to the area E and allotment rents equal to the area $A + B + C$. The capitalized value of $P_s Q_a$ represents the market value of Q_a acres of land and allotment. The allotment alone has a market value equal to the capitalized value of $A + B + C$ on this class of land.

Paper No. 5121 of the Journal Series of the North Carolina Agricultural Experiment Station, Raleigh.

[1] Allotment values are price determined and represent rents in the aggregate. Allotment value is a cost of production and not a rent to the individual firm.

[2] Economic rent is a much used and seemingly simple concept. Yet, as Mishan (1959, 1968, 1969), Shepherd (1970, 1971), Wessel, and others have shown, the concept is ambiguous and confusing even in theory.

[3] These differences may be due to restrictions on the mobility of allotments, as well as variations in land quality. In either case, there are differences in the effect on land values due to changes in the allotment.

[4] All inputs, except land, are assumed to be perfectly elastic in supply for the particular class of land in question. Payment to land is total gross receipts per acre minus payments to all other factors of production.

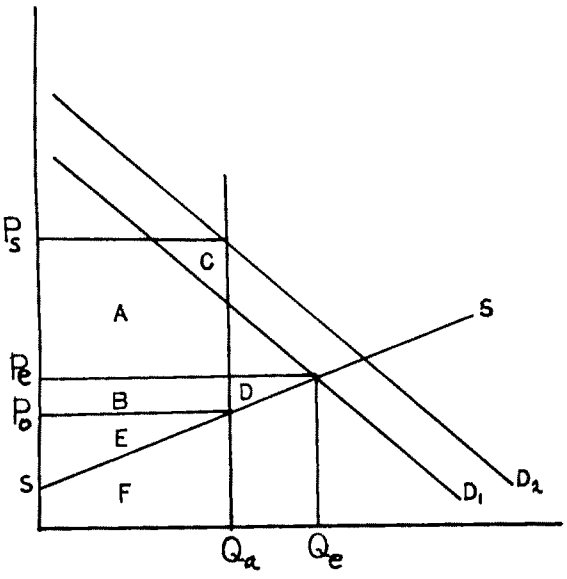

Figure 1. Illustration of allotment and land rents

What happens to the producer's wealth and land values in the situation depicted in figure 1 if the allotment program is abolished? Land used in the production of this crop expands to Q_e. Annual per acre payments to land fall from P_s to P_e (the opportunity cost of Q_e acres of land). Annual allotment rent falls to zero. However, as land used in the production of this crop is increased from Q_a to Q_e, the loss in allotment rent is offset to some extent by increases in land rents (area $B + D$). The annual loss in rent in this case is only the area $A + C - D$. The area B is captured as land rent instead of allotment rent. The wealth loss to allotment holders in the form of reduced land prices is the capitalized value of $A + C - D$, not $A + B + C$, and, hence, is less than the market value of the allotment (the capitalized value of $A + B + C$).

Land Productivity and Rent

Figure 1 illustrates the industry-wide effect on land rents and allotment rents when an allotment is eliminated. The specific effect of a change in allotment value depends on the class of land to which the allotment is attached. The direction and magnitude of the change in land rent for each land class depends on the relationship between P_s (the annual marginal value of Q_a acres of land with the price-support, acreage-restriction program in effect), P_e (the annual marginal value of land if no price-support, acreage-restriction program is in effect), and P_o (the annual marginal opportunity cost of Q_a acres of land). Four possibilities exist.

In case 1, $P_s > P_e = P_o$. This situation is illustrated by figure 2. The area C represents annual land rent, and the area $A + B$ represents the annual

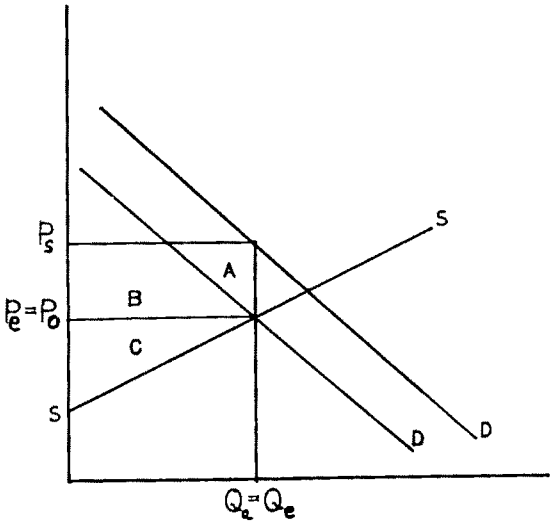

Figure 2. Land rent not affected by allotment removal

allotment rent. The capitalized value of $A + B$ represents the amount by which allotment rights increase the market value of this class of land.

When the allotment is abolished, the annual per acre land payment falls to P_e. In the situation illustrated by figure 2, the amount of land used in the production of this crop does not change since $P_e = P_o$ at Q_a. However, annual rents accruing to landowners who previously had allotments are reduced because allotment rents are eliminated. The per acre value of land decreases by the capitalized value of the annual allotment rent $(A + B)$.[5]

Case 2, $P_s > P_o > P_e$, is illustrated in figure 3.[6] With the existence of the allotment Q_a, annual land rents are represented by the area $D + E + F + G$ and allotment rents by the area $A + B + C$.

The amount of land used to produce this crop is reduced from Q_a to Q_e when the allotment program is abolished, since the opportunity cost of land under the allotment program (P_o) is greater than the marginal land value after allotments are abolished (P_e). The land withdrawn from production of this crop incurs a loss in value equal to the capitalized value of A plus F (i.e., a portion of both the allotment and land rent).

Similarly, there is a decrease in the value of land remaining in the production of the crop equal to the capitalized value of $B + C + D + E$. Thus, in this case, land values decrease by more than the capitalized value of allotment rents $A + B + C$, and land is removed from the production of the crop.

[5] This case also includes the situation where the supply of land is perfectly elastic at P_o. In this case, there are no land rents, and capital losses from abolishing the allotment program are exactly equal to the capitalized value of the stream of allotment rents.

[6] In reality, allotment programs, when instituted, reduce use of all classes of land. Subsequent changes in technology or opportunity costs of competing land uses, however, could result in the situation depicted in figure 3.

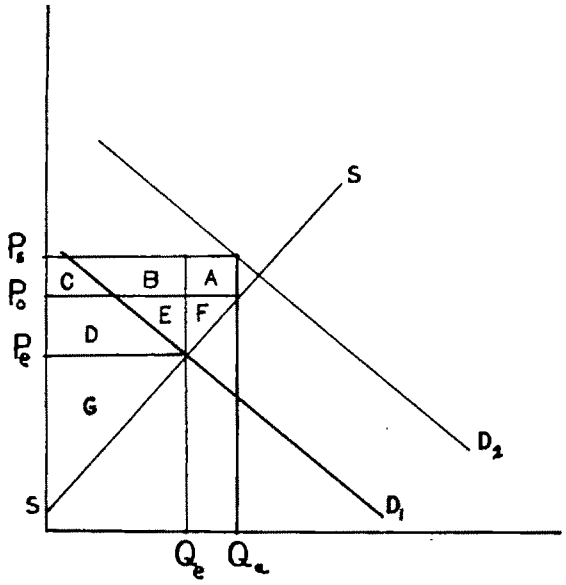

Figure 3. Land rent decreased by allotment removal

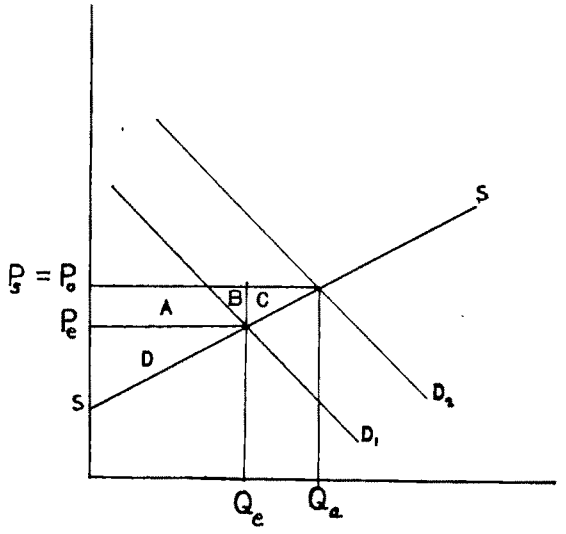

Figure 4. Zero allotment rent

The per acre loss in value of land withdrawn from production when the allotment is abolished is less than the value loss for land that remains in production of this crop. However, in both cases, the decline in land value exceeds the capitalized value of allotment rents.

Case 3, $P_s > P_e > P_o$, is illustrated by figure 1. As shown earlier, the decrease in land values is less than the capitalized value of the allotment. The change in the total value of this class of land when allotments are abolished depends on the relative magnitudes of area $A + C$ and area D. Possibly, D will exceed $A + C$, and total land values could be increased by the removal of allotments.

Case 4, $P_s = P_o > P_e$, is illustrated by figure 4. In this case, there are no allotment rents, since the allotment is not an effective constraint on output. Annual land rents equal $A + B + C + D$.

Production of the allotted crop declines when the allotment program is abolished, since the opportunity cost of land exceeds the marginal value of Q_a acres of land under a competitive product market. The reduction in product price reduces annual land rents and, therefore, land values. The value of land removed from the production of this crop declines by the capitalized value of C. Land remaining in production of this crop is reduced in value by the capitalized value of $A + B$. Average land prices decline, even though the allotment is not an effective constraint on production and has no capital value itself (apart from its effect on land rents).

If no specialized inputs exist and land is perfectly elastic in supply, there are no land rents, and the entire value of the price-support program is reflected in allotment rents. If, on the other hand, land is completely specialized and land supply perfectly inelastic, the entire value of the price-support program is reflected in land rents. Neither of these polar cases are relevant, however, in analyzing the relationship between allotment rents and land rents for most real world allotment and price-support programs. In real world cases where land is partially specialized so that land supply is upward sloping, allotment programs affect land rents.

The elasticity of supply of a particular class of land decreases as the number of alternative uses of this land decreases. The effect (of allotment removal) on market values of land increases as the supply elasticity of land decreases. The more inelastic land supply, the more land rents increase to offset the loss in allotment rents when price supports and allotments are abolished. Stated differently, increases in land rents offset more of the loss in allotment value as the more inelastic is the supply of land.

In reality, allotment values are observed to vary widely from county to county and from state to state. In the case of peanuts and tobacco, land and allotment rents vary within and between states. Higher allotment rents are found in areas that have more specialized inputs in producing the product in question. However, one cannot conclude that producers in areas where allotment rents are highest suffer the largest windfall losses when allotments are abolished. It can be expected that price increases of land and other specialized inputs offset more of the loss in allotment rents in such areas when allotments are abolished.

Empirical Application

Results of a recent analysis of the peanut program are consistent with the above theory.[7] Peanut al-

[7] Several alternatives to the current peanut price-support and

lotment rents are found to be higher in Florida and Georgia than in other peanut-producing states. The study revealed that under yields and prices existing in 1973 the abolition of peanut allotments and allotment rents in these states would have been accompanied by significant increases in land rents due to the states' comparative advantage in producing peanuts.

The study of alternative peanut policies estimates peanut allotment rents and the capital losses that would be incurred in eliminating the current allotment program. The estimated annual rent per acre of allotment[8] (shadow price of peanut allotment) is shown in table 1 for the producing areas examined in the study. The rental values shown in the first column of table 1 are estimates of the differences between P_s and P_o for the allotted acreage for each region in 1973.

The support price for peanuts in 1973 is 16.2¢ per pound. The estimated 1973 equilibrium price in a free market setting is 13.0¢ per pound. Thus, the support price exceeds the estimated equilibrium price by 3.2¢. An estimate of $P_s - P_e$ per acre in each region is obtained by multiplying average yield in the region by 3.2¢ per pound (table 1). This is an estimate of the net reduction in rents that would have occurred as a result of abolishing allotments.

The marginal value of peanut land after the allotment program is abolished (P_e) minus P_o is an estimate of the portion of allotment rent that is captured as land rent if the allotment program is abolished. This can be estimated as $P_e - P_o = (P_s - P_o) - (P_s - P_e)$. These estimates are shown in the third column of table 1. The larger the number, the greater the comparative advantage the area has relative to other areas in producing peanuts.

These data are consistent with the hypothesis that case 3 (figure 1) is the predominant characterization of peanut production in all regions, except the nonirrigated lands in Texas. The marginal value of the land used in the production of this crop in the absence of price supports is higher than the supply price at the current allotted level of production. Under these conditions, abolishing allotments increases production (as explained above), and the resulting increase in land rent offsets some of the decrease in allotment rent.

Peanut production in nonirrigated areas of Texas exhibits the characteristics of case 2 (figure 3), where the supply price at the allotted quantity (P_o) exceeds the equilibrium marginal land value in the absence of an allotment program (P_e). Thus, if the peanut allotment program had been abolished in 1973, land would have been withdrawn from peanut production in the dryland farming area of Texas.[9] In addition, the market value of land then in peanut production would have declined. Moreover, the decline in land values would have been greater than the capitalized value of the allotment as illustrated by figure 3.

Peanut production is expected to expand in all other producing regions if the allotment program is abolished. This is generally accompanied by a decline in the market value of land currently associated with the allotment. However, the decline in the market value is less than the capitalized value of annual allotment rent, as illustrated by figure 1 and the numbers in the third column of table 1. Land currently in peanut production decreases in value by an amount equal to the capitalized value of $P_s - P_e$. The value of additional land brought into peanut production increases in value by the capitalized value of $P_e - P_o$. This increase in land value offsets some of the capital losses on allotment land. In the cases of Georgia and Florida, the values of $P_e - P_o$ and $P_s - P_e$ are almost equal. In these states, the decline in the total value of land suitable for peanuts might be quite small, since peanut acreage is predicted to expand by 78% in Georgia and 133% in Florida as a result of allotment removal.[10]

Summary

If land is the only specialized input, as assumed in this note, all rents can be attributed to land and

acreage-allotment program were considered. A linear programming model was used to compare the effects of the three alternative policies on geographic location of peanut production, producer and consumer surplus, treasury costs, and value of allotments (Nieuwoudt, Bullock, and Mathia 1976b).

[8] Calculated using average yield for the region.

[9] The programming model of the study indicates that peanut acreage is reduced by about 50% in Texas if the allotment program is replaced with a free market policy (Nieuwoudt, Bullock, and Mathia 1976b).

[10] Values of $P_e - P_o$ shown in table 1 are estimates for marginal increase in acreage. The value of $P_s - P_e$ decreases when acreage expands, since the supply curve is upward sloping. Thus, even if peanut acreage expands by 100% when allotments are removed, the total value of peanut land decreases where $P_s - P_e$ and $P_s - P_o$ are equal at the current allotment acreage.

allotments. If other inputs are also specialized, they too earn rents, and a price-support program affects the level of rents. In this case, the model loses some of its ability to predict the effect of a change in allotment rents on land prices, since any change in rents to specialized factors affects the prices of all such factors (not just land prices).

The basic rent model developed should be useful in analyzing differential effects of other price-support and allotment programs on land values by production region. It can easily be modified to analyze the effect of price-support programs where the allotment is made in units of output (poundage quota, milk base, etc.).

Impact of Farm Size on the Bidding Potential for Agricultural Land: Comment

G. A. Whitmore

In a recent issue of this *Journal*, Harris and Nehring (H-N) present a theoretical model of the maximum bid price for agricultural land and an application of the model to cash-grain farms in Iowa. This comment identifies a numerical error in their work, which, when corrected, reveals a conceptual flaw in their model. A revised model is formulated and its application is illustrated using the H-N data.

The Harris and Nehring Model

H-N state their model in equation (1), where the maximum bid price per acre B is defined as the solution of the following expected utility equation:

$$u(x) = E\{u(x + z - B)\}, \tag{1}$$

where x is a fixed (i.e., nonrandom) level of assets, z is a random variable denoting the value of an acre of land, and u denotes the utility function of the farmer. To solve equation (1) for B, H-N use an approximation that requires the calculation of Pratt's measure of local risk aversion from the formula $r(x) = 0.6984/x$. For the asset levels reported in their table 1 for five classes of Iowa farms, the $r(x)$ values given in the same table are all in error by a factor of 1,000. Adjusting the $r(x)$ values by this factor and performing the requisite calculations, the risk premiums reported in their table 4 shrink by a factor of 1,000. For example, the risk premium for an acre of a class IV farm changes from \$77.04 to \$0.08. The latter figure is absurdly small and leads one to question the suitability of the H-N model.

The defect in the H-N model is found in equation (1). A proper formulation of this valuation model would acknowledge that x and z are correlated random variables. The variable x is random because the present value of future after-tax income from farm and nonfarm sources is risky, and x and z are correlated because the present value of after-tax income from an additional acre of land covaries with the economic value of the farming enterprise as a whole.

A Revised Model

In correcting the H-N model, it is helpful to adopt new notation. Let the economic net worth of the farmer, based on farm and nonfarm net incom sources, be denoted by random variable X, and le the after-tax value of an acre of land be denoted b random variable Z. The farmer's utility function fo wealth, measured in present value terms, is denote by u. Finally, p denotes the value of land and othe capital assets that are required (or released) by a expansion (or contraction) of a farm's size by on acre. The term "other capital assets" refers to in vestment changes in equipment and building necessitated by a change in the scale of operations

Given that the size of a farm can be altered at price of \$$p$ per acre, a change of m acres in a farm' size yields the following expected utility to th farmer:

$$E\{u[X + m(Z - p)]\}. \tag{2}$$

The value of equation (2) depends on the farmer' utility function u and the probability distribution o $X + m(Z - p)$. To keep the development simple suppose the utility function has the exponentia form $u(w) = -\exp(-rw)$ and that X and Z have bivariate normal distribution. Letting c denote th certainty equivalent of equation (2), its value unde these assumptions can be shown to be

$$c = E[X + m(Z - p)] - r\sigma^2[X + m(Z - p)]/2 \tag{3}$$

where E and σ^2 denote expectation and varianc operators, respectively, and r is Pratt's measure o local risk aversion (i.e., $-u''/u' = r$ when $u(w) = -\exp(-rw)$).

If the farmer's present amount of land is optimal then c should attain a maximum at $m = 0$. Using th properties of E and σ^2 operators to expand th terms on the right-hand side of equation (3) an setting the first derivative with respect to m equal t zero gives

$$E(Z) - p - r[\sigma(X, Z) + m\sigma^2(Z)] = 0, \tag{4}$$

where $\sigma(X, Z)$ denotes the covariance of X and Z. $m = 0$ corresponds to an extremum, then it mus satisfy equation (4). Setting $m = 0$ in equation (4 gives, after some rearrangement,

$$p = E(Z) - r\sigma(X, Z). \tag{5}$$

From equation (5), the marginal value of an extr acre of land (and the extra capital assets that ar needed to farm it) equals the expected value of a acre $E(Z)$ minus a risk premium $r\sigma(X, Z)$ that de pends on the farmer's risk aversion and th

G. A. Whitmore is a professor of statistics with the Faculty of Management, McGill University, Canada.

covariance between the value of the extra acre and the farmer's net worth.

Implications of the Revised Model

Equation (5) is the corrected analog of H-N's equation (9), which, in the notation of this paper, has approximately the following form:

$$B = E(Z) - r\sigma^2(Z)/2. \tag{6}$$

Contrasting equations (5) and (6), a number of differences are noted. First, B and p do not have synonymous interpretations. H-N incorrectly interpret B as the maximum bid price per acre, whereas it exceeds this price by the value of capital assets that are needed to farm an extra acre of land. Second, in H-N's formulation, the utility function u is a power function that makes the measure of risk aversion r dependent on the farmer's net worth. In the revised model presented here, the exponential function has been used in place of the power function to simplify the mathematical development. Conceptually, there is no difficulty in assuming that u and the probability distribution of $X + m(Z - p)$ have different functional forms than those assumed here. However, the adoption of other forms is likely to be accompanied by less tractable analytical results. In spite of the fact that r in equation (5) is assumed to be a constant for any specific farmer, it is free to vary among farmers so as to reflect diverse attitudes toward risk bearing.

Third, the major difference between equation (5) and (6), and the one that led to the revised model, is the magnitude of the risk premium. The risk premium of equation (5) tends to be substantially larger than that in equation (6) for the following reason. By definition, $\sigma(X, Z) = \rho\sigma(X)\sigma(Z)$, where ρ is the correlation coefficient of X and Z. The values of ρ and $\sigma(X)$ both depend on the proportion of the farmer's net worth derived from nonfarm income and also on the income tax structure, since X is computed on an after-tax basis. If the farmer's net worth derives almost completely from his farm operation, then ρ is close to one and, as shown later, the ratio of risk premium $r\sigma(X, Z)$ to risk premium $r\sigma^2(Z)/2$ is about two times the farm acreage. This explains why the risk premiums obtained from H-N's model seem unreasonably small.

Using equation (5), one can follow H-N's lead and study the *ceteris paribus* effect on p of differential changes in key parameters such as the marginal tax rate, the measure of risk aversion, and so on. Their analysis is not redone here because it is readily duplicated using equation (5) in lieu of H-N's equation (9). It is interesting, however, to consider some new insights into the theoretical aspects of their topic that are provided by the revised model but not by H-N's original model.

First, equation (4) can be rearranged to give a demand schedule for farm acreage m as a function of price p of the following form:

$$m = \frac{E(Z) - r\sigma(X, Z) - p}{r\sigma^2(Z)}. \tag{7}$$

The demand schedule is linear in p with a downward slope of $\$r\sigma^2(Z)$ per acre.

Next, observe that the certainty-equivalent value of the farmer's equity is

$$c = E(X) - r\sigma^2(X)/2. \tag{8}$$

This represents the minimum cash amount the farmer would accept for his ownership claim on the farm and nonfarm assets.

To present additional conceptual insights provided by the revised model, it is helpful to posit the nature of the functional relationship between X and Z. This also accommodates a subsequent numerical illustration. Assuming that a farmer has an n-acre farm with fixed debt obligations (valued after tax adjustments) of L, the farmer's equity is $X = nZ - L$. Since L can be viewed as nonrandom, this relation between X and Z implies that $E(X) = nE(Z) - L$, $\sigma(X, Z) = n\sigma^2(Z)$, and $\sigma^2(X) = n^2\sigma^2(Z)$. Thus, the certainty-equivalent value of the farmer's equity X, as defined by equation (8), is

$$c = nE(Z) - rn^2\sigma^2(Z)/2 - L. \tag{9}$$

Substituting $n\sigma^2(Z)$ for $\sigma(X, Z)$ in equation (5) gives the price per acre

$$p = E(Z) - rn\sigma^2(Z). \tag{10}$$

Using equation (10), equation (9) may be simplified to

$$c = np - L + rn^2\sigma^2(Z)/2. \tag{11}$$

Interpreting equation (11), the first term np represents the total market value of the n-acre farm. Subtracting L to obtain $np - L$ yields the market value of the farmer's equity. Finally, the term $rn^2\sigma^2(Z)/2$ represents the farmer's surplus, i.e., the excess of the certainty-equivalent value of the farm over its market value. The term "surplus" is used because it equals the triangular area under the demand schedule in equation (7) above the market value p.

An interesting by-product of the valuation model developed in this comment is a measure, albeit a crude one, of the bankruptcy risk of a farm operation. For the case in which $X = nZ - L$, bankruptcy occurs if $nZ < L$ because in this situation the economic worth of the farm is less than its liabilities. Since Z has been assumed to have a normal probability distribution, the probability of bankruptcy is found readily from normal probability tables given values for n, $E(Z)$, $\sigma(Z)$, and L. The calculation is illustrated below. Since the actual occurrence of bankruptcy involves complicated intertemporal dynamics, the measure of bankruptcy probability provided by this model must be viewed only as an approximation to the real risk of insolvency.

Table 1. Illustrative Valuation Results for Five Classes of Iowa Cash-Grain Farms and Farmers

	Farm Class				
	0	I	II	III	IV
Farm size (acres), n	1,307	630	390	254	170
Expected value per acre, $E(Z)$	439.25	567.17	520.64	426.04	308.21
Variance of value per acre, $\sigma^2(Z)$	6,815.5	11,363.2	10,306.5	6,507.8	10,499.4
Measure of risk aversion, r	2.98×10^{-6}	5.98×10^{-6}	6.99×10^{-6}	7.09×10^{-6}	14.67×10^{-6}
Price per acre, p	412.70	524.36	492.54	414.32	282.03
Risk premium per acre, $E(Z) - p$	26.55	42.81	28.10	11.72	26.18
Expected value of equity, $E(X)$	234,167	117,489	99,953	98,568	47,616
Certainty equivalent value of equity, c	216,813	104,004	94,473	97,079	45,391

Value of debt obligations, L	339,933	239,828	103,097	9,646	4,780
Expected value of farm, $nE(Z)$	574,100	357,317	203,050	108,214	52,396
Market value of farm, np	539,399	330,347	192,091	105,237	47,945
Bankruptcy probability, $P(nZ < L)$	0.015	0.040	0.006	0	0.003

Applying the Revised Model to Harris and Nehring's Data

It is informative to apply the formulas developed above to H-N's data on five classes of Iowa cash-grain farms. The numerical results should be considered as illustrative only, since, as H-N correctly point out, the data are unreliable in the extreme and are derived from many crude assumptions. The values of r used in table 1 have been adjusted by a factor of 1,000 to rectify the numerical error in the H-N article. The "net worth" value given by H-N is assumed to represent $E(X)$, the expected value of the farmer's equity. The assumption that $X = nZ - L$ eliminates explicit consideration of the tax structure and nonfarm income sources. In spite of the degree of abstraction involved and the shortcomings of the data, the numerical results still seem reasonable. The risk premium per acre varies from \$11.72 for a class III farm to \$42.81 for a class I farm (table 1). The surpluses for these farms range from \$17,347 to \$1,488, decreasing with the size of farm except for the smallest farm class. This means for a class 0 farm that \$17,347 in excess of its market value (based on a marginal valuation of its land and other capital assets) would have to be paid to purchase it. The size of farm debt obligations are surprisingly realistic given the oversimplified model used to derive them, i.e., the model $X = nZ - L$. Debt amounts increase steadily with farm size. For class III and IV farms, debt-equity ratios (based on the market value of equity) are quite small. For the three largest classes of farms, the debt-equity ratio ranges from 1.16 for a class II farm to 2.65 for a class I farm. The latter ratio seems too large and casts suspicion on H-N's data for this farm class. To illustrate the calculation of a bankruptcy probability, using table 1 for farm class 0, $nE(Z) = 574{,}100$, $L = 339{,}933$, and $n\sigma(Z) = 107{,}901$. Thus, nZ must fall more than $(574{,}100 - 339{,}933)/107{,}901 = 2.17$ standard deviations below its mean for bankruptcy to occur. Consulting a normal probability table gives the corresponding bankruptcy probability as 0.015. The bankruptcy probabilities for the five classes of farms are shown in table 1. As noted already, the debt-equity ratio for the class I farm is anomalous, and this accounts in part for the large bankruptcy probability for this class of farm.

Impact of Farm Size on the Bidding Potential for Agricultural Land: Reply

Duane G. Harris and Richard F. Nehring

Whitmore's comment identifies a numerical error in our empirical illustration and contends that our bid-price model is thus conceptually inadequate. While there is indeed a mistake in our numerical illustration, although not the one Whitmore purports to discover, that error in no way invalidates the conceptual foundations of our model. Furthermore, in his extension of our model, Whitmore inadvertently contrasts the results of our bid-price model with a certainty-equivalent model. Finally, Whitmore's certainty-equivalent approach itself generates a questionable theoretical model.

The purpose of this reply is to acknowledge and clarify the numerical and reporting errors contained in the original paper and to evaluate Whitmore's theoretical criticism of our model. The numerical clarification is presented in the next section. Whitmore's theoretical argument is considered, a correct extension of the bid-price model is presented, and some final comments are offered.

Numerical Clarification

Unfortunately, our numerical illustration contains both a reporting error and a calculation error. The reporting error is the one that leads Whitmore to question the validity of our results. To make our analysis compatible with the LDM utility function, it is necessary to define wealth and income in thousands of dollars. In our calculations we did so. In table 1, however, we chose to report the results in dollars rather than thousands of dollars. Thus, the measure of risk aversion, $r(x)$, was reported as used in the calculations rather than as appropriate for income and wealth defined in dollars. While an incorrect measure of $r(x)$ was reported, the bid prices were correctly calculated and reported as far as the measure of risk aversion was concerned.

The calculation error involves an incorrect scaling procedure on variability of income per acre. We mistakenly scaled the variance of income in thousands of dollars rather than the standard deviation. Thus, the bid prices were in error, much as Whitmore contends, but for a different reason. Corrected per acre bid prices for classes 0, I, II, III, and IV are \$439.24, \$567.14, \$520.60, \$426.02, and \$308.13, respectively. None of the tentative conclusions regarding relative bidding potentials are changed. The same bid-price rankings remain among the five farm-size classes.

The most misleading interpretation of our numerical results is that the difference between the risk-neutral bid price and the risk-averse bid price is defined as the risk premium. That interpretation is not consistent with Pratt's framework, but our interpretation evidently leads Whitmore to question the theoretical underpinnings of the bid-price model.

Whitmore's Revised Model

To evaluate Whitmore's revised model and to contrast it with our bid-price model, it is useful to state the conceptual differences between a bid price and an ask price or certainty-equivalent price. In Whitmore's and our notation, for a given level of wealth x, the asking price for z, a risk, is given by Pratt's equation (3a):

$$u(x + c) = E\{u(x + z)\}, \tag{1}$$

where c is the minimum asking price or certainty equivalent of z. Equation (1) establishes the behavioral relationship that the decision maker's utility from original wealth plus the certain asking price for the risky asset is at least as great as the expected utility from the portfolio that includes the risky asset. The risk premium π is defined by Pratt as the expected value minus the certainty equivalent:[1]

$$\pi = E(z) - c. \tag{2}$$

As Pratt cautions, the minimum asking price c must be distinguished from the bid price B, given by Pratt's equation (3b):

$$u(x) = E\{u(x + z - B)\}. \tag{3}$$

Equation (3) establishes the behavioral assumption that the decision maker pays a price for a risky asset such that the expected utility of his resulting

Journal Paper No. J-8703 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa, Project No. 2066. The authors wish to thank William F. Hampel, Jr., for helpful comments during the development of this paper.

[1] Our reference in table 4 to the risk premium as the difference between the risk-neutral bid price and the risk-averse bid price is not consistent with the framework outlined by Pratt. Our interpretation involved the quantity $[E(z) - B]$ rather than $[E(z) - c]$.

position is no less than the utility of his original wealth position, which does not include the risky asset. In his criticism of our bid-price model, Whitmore reverts to the development of a certainty-equivalent model. Although Whitmore's certainty-equivalent analysis offers some useful insights, it does not generate results equivalent to a bid-price model.

Whitmore contends that the basis for the conceptual flaw in our bid-price model is that the model does not consider initial wealth as a random variable and thus does not accommodate correlation between the risky asset and the original wealth position. He is correct in his assertion about our treatment of wealth as certain, but that property of the model hardly can be considered a conceptual flaw. Unfortunately, Whitmore's attempt to extend the bid-price model utilizes questionable procedures and produces theoretically questionable results.

Whitmore defines p as the "value of land and other capital assets required to expand a farm's size by one acre." From his equation (3), which gives the certainty-equivalent expression incorporating random wealth,[2] he derives equation (5) for p as

$$p = E(z) - r\sigma(x, z), \tag{4}$$

where r is the measure of risk aversion, $\sigma(x, z)$ is the covariance between x and z, and $r\sigma(x, z)$ is Whitmore's definition of a risk premium.

In deriving equation (5), Whitmore first maximizes his equation (3) with respect to m, the number of acres added to original wealth, and then sets m equal to zero in his solution for p. Maximization of equation (3) with respect to m gives the additional acreage m^* that maximizes the certainty-equivalent of the farmer's wealth position. But by then setting m equal to zero, Whitmore solves not for the value of land and other capital assets required to expand a farm's size by one acre but rather for the land price at which the farmer's existing wealth position is optimal. In his definition, m equals one, but in his optimization procedure, m equals zero. Thus, his solution value of p is inconsistent with his original definition of p.

Furthermore, he claims that his equation (5) is the corrected analog of our equation (5), which in his notation appears as his equation (6) and has the following form:

$$B = E(z) - r\sigma^2(z)/2. \tag{5}$$

But Whitmore's equation (6) is not our bid-price equation in his notation. It is his certainty-equivalent equation in our notation.

In addition, Whitmore's "corrected analog" produces a curious result for the case in which wealth is certain. His equation (5) can be rewritten as

$$p = E(z) - r\rho\sigma(x)\sigma(z), \tag{6}$$

where ρ is the correlation coefficient between x and z. From equation (6), if z is risky but wealth is certain—$\sigma(x)$ equals zero—Whitmore's risk premium is zero. In other words, Whitmore is saying that, if wealth is certain, there is no risk premium on a risky asset, regardless of the degree of risk aversion of the investor. That result, as a special case of the general result in his equation (5), makes the model suspect.

Random Wealth and the Maximum Bid Price

To extend our original bid-price model to accommodate uncertain wealth and its correlation with the risky asset, a random element can be introduced into the initial wealth position. Let

$$V = x + v, \tag{7}$$

where x is now the beginning-of-period net worth of the decision maker and v is the random dollar change in his beginning-of-period net worth position over the period. Thus, V is the random value of beginning wealth as measured at the end of the period. Assuming

$$E(v) = 0 \tag{8}$$

and defining

$$\text{var } v = \sigma_v^2, \tag{9}$$

then

$$E(V) = x \tag{10}$$

and

$$\sigma_V^2 = \sigma_v^2, \tag{11}$$

where $E(V)$ and σ_V^2 are, respectively, the expected value and variance of the investor's initial wealth position at the end of the period; that is, the investor expects that, on average, the end of period value of his beginning net worth is equal to its beginning value. Also, if we assume that the investor purchases m acres of land, the bid price per acre is given by the equation

$$E[u(x + v)] = E[u(x + v + mz - mB)]. \tag{12}$$

Equation (12) establishes the behavioral assumption that the decision maker pays a price for a risky asset such that the expected utility of his resulting wealth position is no less than the expected utility of his original wealth position, which did not include the additional risky asset. The assumption is made that the investor does not alter his existing portfolio other than to purchase the asset mz.

By using a Taylor series to expand u around x and by utilizing Pratt's measure of local risk aversion,

$$r(x) = -\frac{u''(x)}{u'(x)}, \tag{13}$$

[2] Whitmore's derivation of the certainty-equivalent equation (3) involves truncating the Taylor expansion on one side of the equation after the linear term but on the other side after the quadratic term. All our derivations include the quadratic term on both sides of the equation.

equation (12) may be approximated by

$$(14)\quad \tfrac{1}{2}mr(x)B^2 - [mE(z)r(x) - 1]B + \left[\tfrac{1}{2}mr(x)\left\{\left[\sigma_z^2 + \frac{2}{m}\rho\sigma_v\sigma_z\right] + [E(z)]^2\right\} - E(z)\right] = 0.$$

Solution of this quadratic equation gives B in terms of $r(x)$, $E(z)$, m, σ_z, σ_v, and ρ:

$$(15)\quad B = E(z) - \frac{1}{mr(x)} \pm \left\{\frac{1}{[mr(x)]^2} - \left[\sigma_z^2 + \frac{2}{m}\rho\sigma_v\sigma_z\right]\right\}^{\frac{1}{2}} \text{ for } r(x) \neq 0;$$

$$B = E(z) \text{ for } r(x) = 0.$$

Incorporation of random initial wealth in the bid-price model results in a new formulation of our original equation (5), which includes the term $-\frac{2}{m}\rho\sigma_v\sigma_z$ in the square root portion of the bid price. Thus, as the covariance between initial wealth and the risky asset increases, the maximum bid price for the risky asset decreases. This is consistent with the thrust of Whitmore's argument. Also, if original wealth is certain—σ_v equals zero—equation (15) collapses into our original equation (5) for the case in which m equals one. Thus, the bid price for one additional acre for the certain wealth situation is but a special case accommodated by the more general bid-price model in equation (15). (For a more extensive discussion of the properties of a bid-price model under wealth uncertainty, see Harris and Hampel.)

Concluding Comments

Whitmore criticizes our development of a model in the context of a certain original wealth position. We agree that investors' wealth positions are likely to be uncertain, and thus we compliment Whitmore on the spirit of his extension of our model. In the exposition of his numerical results, however, Whitmore's assumptions become as contrived as ours. Specifically, he considers the situation in which a farmer sells one acre of land in order to buy an identical one.

Also, as noted, the difference between the bid price and the expected value of a risk does not represent the risk premium. Other research indicates that the bid price for a risk averter can be either greater or less than the expected value, depending upon the relative risk associated with the original portfolio as opposed to the new risk. (See Hampel and Harris for an elaboration of the relationship of the bid price to the expected value of a risk.) Thus, Whitmore's assessment that our risk premiums are "absurdly small" becomes irrelevant because we did not derive risk premiums as defined by Pratt.

Finally, there are many theoretical and empirical issues yet to be settled in the formulation of bid prices. For example, our model, even as modified, suffers from an inappropriate treatment of income taxes and from an awkward handling of the opportunity cost of equity. Whitmore has pursued an important extension of our original model. Adams and Hampel and Harris have likewise made inroads into some of the issues. But there is certainly much room for additional analysis if bid-price models are to offer richer insights into the ownership structure of and investment strategies for participants in U.S. agriculture.

Transfer of Development Rights: An Analysis of a New Land Use Policy Tool: Comment

Mark R. Bailey and Clayton W. Ogg

In view of the large number of innovative land preservation measures that have recently been proposed, Barrows and Prenguber's attempt to identify possible economic problems of a transferable development rights (TDR) program is both interesting and timely. Their discussion, however, enumerates a number of problems that appear to make such a program virtually unworkable. The TDR program as conceived by the authors hardly compares favorably to other preservation measures being considered by planners and policy makers across the country (Bryant, Sargent). Many of the problems specified by Barrows and Prenguber (B&P) are not necessarily inherent in the TDR program per se but rather result from the assumptions and restrictions they employ. Following some specific criticisms of the B&P arguments, a static model is offered in an attempt to suggest more realistic problems and research needs concerning implementation of TDR programs.

The major criticism that B&P offer is that fair or full compensation would not be guaranteed to restricted land owners under a TDR program. Other criticisms center upon potential monopoly problems, forecasting locational demands, timing problems, and discontinuous supply curves. B&P's discussion of these problems is somewhat incorrect. They base most of their objections to a TDR program upon a rather limited analysis of a highway interchange system and then generalize from that analysis to criticize any TDR program. The weakness of some of their arguments results from this extrapolation.

B&P mention two problems on the supply side: the monopoly potential and the possibility of a noncontinuous supply curve. Both of these problems are moot. For a monopoly to form, an individual entity would have to gain nearly total control of the TDR supply. But it is difficult to believe that a potential monopolist could convince all holders of TDR to sell to him. Besides, market regulation could be designed to preclude such an occurrence. It is therefore unclear why the potential for monopoly in a TDR program is greater than it would be in the normal land market.

Mark R. Bailey and Clayton W. Ogg are agricultural economists with the Natural Resource Economics Division, Economic Research Service, U.S. Department of Agriculture.

The views expressed are those of the authors and do not necessarily represent those of the U.S. Department of Agriculture. The authors are grateful for the helpful comments of John E. Hostetler, James Horsfield, and the anonymous reviewer.

Why is a noncontinuous supply curve a special problem? The authors suggest that market uncertainties would result in a noncontinuous supply curve because some DR owners would hold their rights, while less liquid or lower income holders would sell. But such actions are not unique to a TDR market. Does not the same thing occur in the stock market or in commodity trading?

The authors discuss at length possible timing problems in a TDR market brought about if owners of TDR do not sell when there is demand for those TDR. But under less restrictive assumptions, which they eloquently bring to light, timing problems evaporate. A criticism directed toward a TDR program should concentrate on those problems that are unique to the program rather than on those points that are pervasive throughout present land markets. TDR programs are, in fact, designed to ease several land market problems, such as the timing of land use changes, which the authors describe as if they are caused or exacerbated by a TDR program! In particular, TDR land use designations remove land development uncertainty that often precipitates erratic buying and selling.

The value of a TDR is dependent upon development demand, for it is that demand that gives rise to the difference in value between potentially developable land and restricted land. With a weak demand for development, the divergence in value between the two categories of land would be minimal, and thus little compensation would be required. This point is made in B&P's note 3. Nonetheless, B&P contend that professional planners must somehow anticipate where future developmental demand will be strong, so that they can designate those areas as development districts. Such designations, they argue, would guarantee a strong demand for TDR and thus provide fair compensation to the restricted landowners. However, in designating development districts based upon developers' wants, the shoe is on the wrong foot. Planners should first concern themselves with recommending socially optimum development patterns based upon soil capabilities, slope, access to public services, etc. Areas need not and, in many cases, should not be designated strictly according to estimates of prospective developers' locational wants. This is not to say, however, that planners should ignore developers' wants; rather, the primary designation criterion should not necessarily be based upon those wants.

Based upon their model, B&P conclude that for full compensation to be gained by the restricted property owners, unstable TDR prices would have been required. But in their note 12, they state that after the highway interchange was constructed, land assessments were still based upon agricultural values. This explains much of the price divergence of their TDR. Given the fact that TDR are homogeneous and perfectly substitutable, if each property had been assessed according to its locational and physical characteristics, full compensation does not suggest that TDR prices would be unstable. B&P's TDR price divergence would have been minimal; instead, prices of the land would have been divergent because of the advantageous characteristics of some parcels relative to others.

The question of full compensation is dependent upon full and accurate assessments. This point can be clarified with a static model. The model is also relevant to the closely related issue of anticipating development demand. It becomes evident that the example used by B&P involved assumptions that maximized potential TDR problems.

Limiting land designations to density zoning is an unnecessary assumption that adds to the lengthy B&P list of problems, particularly in anticipating development demand. There is no reason to carry this limitation of zoning into a TDR program. Assuming instead that the planning agency simply designates specific areas that should be developed or preserved, the supply of TDR can be based upon the potentially subdividable acres, strictly on an acreage basis.[1] Under this scenario, zoning is handled separately from the land designation under a TDR program. This separates land preservation from other decisions that affect land values.[2]

Like B&P's model, TDR will separate builders' demand for land and allow the right to develop land to be sold separately from the remaining rights to use the resource. The demand curves in figure 1 illustrate the separation of the two demands: D_t represents the original demand for land with all rights included, and D_f represents that portion of demand for land which is due to its potential returns from farming.

Figure 1 sets the original supply of developable land at S_1 with S_2 acres remaining after a TDR program has been implemented. Assuming for the moment homogeneous land acres, a TDR program allows losses in land value in the restricted areas, which are indicated by the cross-hatched rectangle in figure 1, to share some of the benefits in the area where values have increased (represented by the shaded area).

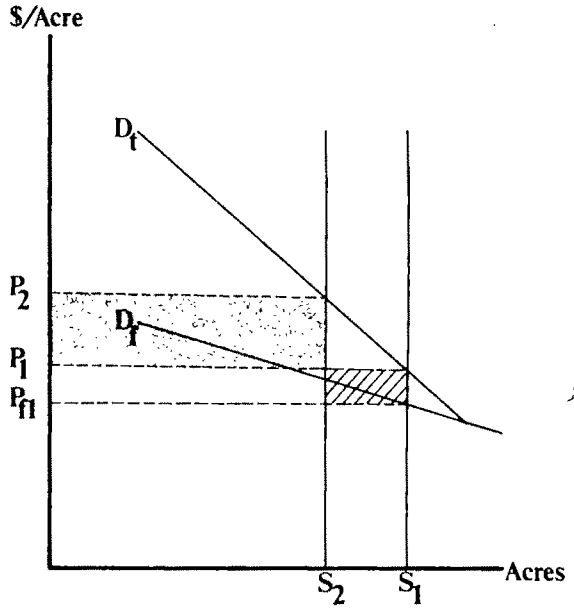

Figure 1. Economic consequences of preserving farmland

Under our assumptions, P_{f1} and P_2 are determined by demand curves that are not shifted by the preservation program.[3] However, P_2 is not itself the price of unrestricted land, for it includes the price of such land and the value of development rights. It is not clear how this value of unrestricted acres is divided between these two markets, although it would be a simple matter for the government to set some price, P_1 for instance, for unrestricted land. This would assure $P_2 - P_1$ as the price for development rights and make it possible for the benefits from the program to be divided between restricted and unrestricted landowners.

Designation of the correct number of TDR to meet overall housing demand clearly ceases to be a major problem, since unrestricted acres can be used in varying intensity according to the demands prescribed by developers.

The potential for economic losses due to downzoning also becomes very manageable by careful designations of land use to maximize the net of losses and gains between restricted and unrestricted areas. (Net gains equal the difference between the shaded area in figure 1 minus the cross-hatched area.) Since rights to the unrestricted acres are divided among all landowners, they share a common economic interest in obtaining social optimum land use designations for their community. If

[1] This correspondence between numbers of development rights and numbers of acres should not be confused with the distribution of these transferable development rights. Fair compensation depends completely on the way this homogeneous commodity is distributed.

[2] While this is more precise than zoning as a means of achieving land preservation objectives, it leaves part of the task of land use control within the "unrestricted area" to traditional zoning methods.

[3] We assume zoning decisions are separate from the TDR program. For representing the final demand for land, use of D_t in figure 1 still involves a simplification in that it ignores the impact of land preservation in raising the utility of owning units of the remaining land (Ogg). This demand shift is not emphasized here, since it does not serve to clarify our differences with Barrows and Prenguber. (It is assumed, of course, that restricting land from development does not appreciably change the supply of land that can be used for other nondevelopmental uses).

land use designations are based upon physical and aesthetic capabilities of the land and if demand for development rights is inelastic, positive net gains to landowners will result. This is true even where substantial acreages are totally restricted.

It should now be even more evident that, since development rights are still a completely homogeneous commodity, prices that owners receive will not vary as they did before DR were separated from the land. If the DR are equitably distributed, a common price for DR does not lead to the unfair losses predicted by B&P for owners in the restricted area.

Although certain criticisms of TDR made in B&P's article have been discredited here, a real difficulty appears when our rather unrealistic assumption of homogeneous acres is dropped. Different landowners start with very different property values due to unique locational and environmental capabilities for development and in land capabilities for other uses. Thus, the problem centers upon the equitable distribution of TDR to landowners.

The most important need for a workable TDR program is the accurate assessment of the value of each individual's original or preprogram development rights so that each may be assigned a fair share of the TDR. Fortunately, land assessment is not a new problem; by focusing on this real need, initiation of a TDR program does not appear to be such a hopeless task.

It is evident that success for TDR may still depend upon fairly restrictive local circumstances and that it may not be economically feasible for many situations where land use control or preservation is desired. TDR may never be politically acceptable anywhere. Nonetheless, careful anticipation of economic impacts under well-defined conditions is a more positive approach than simply listing every possible thing that can go wrong under any hypothetical program or circumstance.

Transfer of Development Rights: An Analysis of a New Land Use Policy Tool: Reply

Richard L. Barrows, Bruce A. Prenguber, and Marvin B. Johnson

We agree wholeheartedly with Bailey and Ogg that "careful anticipation of economic impacts" of TDR is a productive and necessary step in refining the promising concept of TDR. Since the theoretical advantages of TDR have been widely discussed and accepted, researchers should focus on identifying (and solving) the practical problems that may arise in initiating and administering TDR programs. In the initial article, the economic determinants of success in establishing and administering a TDR program were identified, and the impacts of a hypothetical program around a highway interchange were analyzed. The article was not normative—the purpose was not to "object" to TDR nor to show that TDR is necessarily unworkable as a land use policy. The analysis of the highway interchange TDR program revealed several practical and theoretical difficulties that arose when TDR was applied to the complex realities of the development process, and it was suggested that additional research is needed to simulate TDR programs in other environments.

While we agree with Bailey and Ogg that potential TDR impacts should be carefully analyzed, we fear they have misinterpreted much of the argument. First, it was not claimed that DR monopoly would necessarily plague all TDR programs, but we strongly disagree that the potential problem is "moot." If the preservation area is relatively small, or if a large preservation area is held by only a few owners (e.g., farmers), there is certainly potential for one owner to amass a large portion of the outstanding DR. Decision makers wishing to implement TDR programs should not ignore potential DR monopoly problems simply because there may already be monopoly elements in the current development land market.

Second, a TDR program would not necessarily be characterized by a noncontinuous DR supply schedule, nor would such a schedule necessarily doom the program. Instead, it was argued that the "uncertainties of market action by DR holders may not permit the assumption that DR supply will be a continuous positively sloped curve" and that decision makers (and economists) should be aware of this in establishing or analyzing TDR programs (p. 551). Potential problems of the timing of DR supply and demand were noted, and it was argued that these problems could exacerbate current timing problems in the market for development land.

Third, Bailey and Ogg imply that there is no need for planners to anticipate development demand to ensure strong DR prices and "reasonable" compensation. Rather, they argue that if development demand is weak, there is only slight divergence between development and restricted values of land, and very little compensation is required. Clearly, if there is no demand (or weak demand) for developable land, there may be little reason for establishing a TDR program. But the critical question is: How does the DR price compare with the loss of development value incurred by the restricted landowner? It is this comparison that may be used by the courts and the community to determine whether the compensation is "fair." Consider the following cases of TDR development districts (DD) and preservation districts (PD).

(*a*) Small DD, small PD: the planning agency must forecast development demand with some accuracy and establish the DD accordingly. Otherwise, developers may avoid the relatively small DD, and restricted landowners would not be compensated.

(*b*) Small DD, large PD: again, the planning agency must establish the DD such that strong development demand results in compensation to restricted owners. However, the large PD may require that many DR of substantial aggregate value be purchased to ensure compensation.

(*c*) Large DD, small or large PD: unless truly massive urbanization is underway, development may occur many years into the future at the low density that may be permitted in the DD without DR purchase. Compensation may be delayed many years and may jeopardize the legality of the restrictions.

Thus, the problem of low demand for development in the DD cannot be dismissed by the simple argument that low demand necessarily means little compensation is required. In each of the above cases, the development potential in the preservation district might have been quite high prior to the TDR program, yet low DR demand would provide little compensation.

Fourth, the finding that full compensation would have required fluctuating DR prices seems to be quite disturbing. We agree that full compensation

Richard L. Barrows is an associate professor and Marvin B. Johnson is an assistant professor in the Department of Agricultural Economics, University of Wisconsin—Madison, and Bruce A. Prenguber is a natural resource economist with the Washington Department of Natural Resources, Olympia.

does not invariably or logically require fluctuating DR prices, but the question can only be answered by empirical analysis. The fact that DR are perfectly substitutable for each other and that land prices vary does not imply that DR prices "need not fluctuate." In the highway interchange analysis, if the posthighway land assessments had reflected locational value, full compensation DR prices may not have diverged so greatly. The uncertainty arises from the question of whether there were very great inherent differences in locational value among the farmland parcels on the interchange. The different per acre prices that were paid by developers may only reflect differences in bargaining skills, liquidity positions, or other "imperfections" in the market.

However, Bailey and Ogg argue that if locational differences are incorporated in land assessments, DR prices would have shown only "minimal" fluctuations. There is no empirical evidence offered to substantiate this claim. This argument is apparently based on the assumption that the interchange land market (and development process) behaves as the neoclassical model of pure competition suggests; hence, any deviation from the predictions of that model must be due to the researcher's error. We maintain that the stability of DR prices can only be established through empirical analysis of potential (or preferably actual) TDR programs.

Finally, Bailey and Ogg argue that "criticism directed toward a TDR program should concentrate on those problems that are unique to the program." Again, it is incorrect to conclude that the original analysis was a normative criticism of TDR. In any case, it is not clear why an analysis of TDR should be limited to those features unique to the program. If TDR success depends on estimating the strength and timing of development demand, or if property tax assessments are used in distributing DR, then problems with the land market or tax assessment system may doom the program just as surely as problems "unique" to TDR, such as excessively low DR prices or court decisions on TDR's constitutionality.

A troublesome aspect of Bailey and Ogg's argument is the attempt to separate zoning and density from the TDR program. They argue that "zoning is handled separately from the land designation under a TDR program" but also note that "it [TDR] leaves part of the task of land use control within the unrestricted area to traditional zoning methods." This distinction is unclear. Hopefully, a community's land use plan is the basis for designation of preservation and development districts, but the essence of TDR is density restrictions in the development zone that create demand for DR and lead to compensation for restricted owners. It matters little whether these area designations and density restrictions are termed "zoning," but the restrictions are critical to TDR success.

The graphical model advanced by Bailey and Ogg is an interesting application of price theory and illustrates the economic gains and losses in TDR programs. However, the assumptions of the model require more scrutiny, and its usefulness is limited by its static nature.

The meaning of the model's demand curves is unclear. For example, it is assumed that land is homogeneous, yet the farm component (D_f) of total demand (D_t) is represented as downward sloping in figure 1. Why are the potential returns from farming homogeneous acres within a relatively small TDR region declining rather than constant? The nonfarm component of total demand for land is even more confusing. This implicit development potential component to D_t is never identified but presumably represents the discounted present value of the possible future gains associated with developing land rather than farming it. The downward slope of the implicit development demand component can be attributed to differences in owners' and developers' perceptions of future development potential. The homogeneous acres are then ranked along the horizontal axis according to the views (optimistic to pessimistic) of the area's development potential. Alternatively, the demand for development land may be viewed as the perceptions of a single developer extracting all consumer surplus from the development process.

The development component cannot possibly reflect actual demand of development land. If such a demand existed at the time restrictive zoning or TDR was being considered, it would have been realized before any program went into effect. Farmers who hold land at P_1 (or P_2) are speculating that their land will someday be purchased by a developer for considerably more than its farming value. This is implicitly recognized when the farm and development components are vertically added to derive the total demand curve. Such vertical addition requires that the homogeneous acres be identified and ranked. Bailey and Ogg are correct to note that a "real difficulty appears when the assumption of homogeneous acres is dropped." We suspect that a model that adds demand curves horizontally and analyzes the specific acreage allocation to different uses may be more appropriate and useful in analyzing TDR programs. Finally, the assumption that the demand curves do not shift with the onset of TDR must be carefully examined. What area do the curves represent, and what happens if there is any area avoidance by developers? The assumptions of Bailey and Ogg's model certainly deserve more scrutiny, but the model is a first step toward a general theory of TDR markets.

Great care must be taken in discussing the benefits of a TDR program. Bailey and Ogg seem to equate "social optimum land use designations" with maximizing the difference between the gain in aggregate land value in the development zone and the loss in aggregate land value in the preservation zone. This is correct only if private demand for development is based on all social benefits and costs inherent in the development process. But if this were the case, there would be no efficiency

gains from public policies to control land use. Land use controls allocate land through a nonmarket process precisely because the "social optimum land use" pattern does not result from unrestricted private individuals responding to market signals. In terms of Bailey and Ogg's model, the private development demand curve does not reflect the net social benefit from land development. Alternatively, the suggestion that the local government maximize the "net of gains and losses between restricted and unrestricted areas" is equivalent to the dictum that the local government should maximize aggregate land value in the area. In this view the local government acts as a monopolist who sets development land supply to maximize aggregate land value, equivalent to "social optimum land use" only if the development demand curve represents social rather than private returns to development.

While Bailey and Ogg focus on the aggregate benefits and costs of TDR, we believe that the more critical issue is the incidence of benefits and costs. TDR has appealed to many planners and local governments because its cost to government seems to be zero (ignoring administrative costs). While TDR may mean a "free lunch" for local government, someone pays for the change in land policy. The distribution of TDR costs among restricted zone landowners, development zone landowners, developers, and final consumers is not clear (Barrows and Prenguber). The distribution of benefits and costs of TDR programs is a fruitful area for future research.

Welfare Implications of Stabilizing Consumption and Production: Comment

Robert Weaver and Peter Helmberger

In a recent paper Subotnik and Houck consider previous theoretical analyses that compare the effects of price instability (no storage) with the effects of price stabilization (storage) and conclude that price stabilization gives rise to an increase in welfare if one is willing to ignore storage costs. Subotnik and Houck claim this result could be used to justify using buffer stocks. We fail to see how a model that ignores storage costs can be used to justify buffer stocks, public or private. Moreover, welfare analysis of government-held buffer stocks must compare outcomes of regimes with and without government, not with and without storage. Clearly, private storage and speculation may occur in the absence of a government buffer stock scheme.

This brings us to a more important concern with the Subotnik-Houck paper. They propose to extend previous work through analyzing the welfare effects of stabilizing consumption and production. Their model of a free and competitive market assumes that private storage and speculation do not occur. This can be seen most clearly by the manner in which expressions for equilibrium price and quantity are developed. Supply and demand are equated in the tth period, with no consideration given to storage. A model that disallows private storage when the commodity involved is storable is not a model of a free and competitive market and appears to be of limited interest.

If private storage is allowed, then the buffer stock transactions undertaken by the government to stabilize consumption or production, as proposed by Subotnik and Houck, are in error. The reason for this is that the stabilization of consumption (production) gives rise to price instability. Instances might easily arise in which the difference between the current and expected future price exceeds per unit storage costs, which in turn leads to private storage. One can easily think of examples in which the proposed government transactions would be offset by those of the private trade. Consider a situation in which demand is very weak. In order to stabilize consumption, the government sells from its stock, thus depressing price. The private trade looks at the current price and decides that the expected price next year exceeds current price plus storage costs. Therefore, they acquire stocks at the very same time the government is selling its stocks. The government may not be able to achieve its objective.

In modeling government policy that seeks to stabilize variables other than price, Subotnik and Houck have given inadequate attention to the possibility of private storage. The buffer stock transactions that the government uses to achieve its objective must take into account the behavior of the private storage industry. When this is recognized, it is by no means clear that non-price stabilization is a viable government alternative. Writers who have focused on price stabilization have been able to ignore private storage because with positive per unit storage costs, complete price stabilization destroys the private storage industry.[1] It seems imperative that theoretical analysis pay attention to the behavior of private traders if the resulting hypotheses are to be useful in understanding what goals the government might strive to achieve, what buffer stock transactions it might choose to use, and what impact its actions might have on market performance.

[1] Massell has constructed a model of an international buffer stock scheme, assuming zero storage costs and allowing for varying levels of price stabilization. Unfortunately, he, too, neglected the possibility of private storage and speculation in the construction of his formal model. This renders many of his theoretical results for other than the complete stabilization case of limited interest.

Welfare Implications of Stabilizing Consumption and Production: Reply and Extension

Abraham Subotnik and James P. Houck

The purpose of the article criticized by Weaver and Helmberger was not to exhaust reality but to extend the theoretical analysis of stabilization schemes. We wished to see how the already known, abstract measures of welfare and variability change when quantities, not prices, are stabilized by central authority. To introduce private storage explicitly obviously changes the model and damages simple analytical comparisons with previous work. Moreover, one can easily imagine an economy in which private storage (in the commercial sense) is either illegal or heavily taxed. However, the role of private storage is important in an open market economy, and its consideration will lead to a more realistic appraisal of stabilization schemes.

Before formally introducing private storage into the model, we flatly contradict the statement by Weaver and Helmberger that our results are in error because the stabilization of quantity may destabilize price. We say explicitly that "supply stabilization may result in either increased or decreased price variability" (p. 17). The results may lack a measure of realism, but they are not erroneous; at least, Weaver and Helmberger have not shown it.

The core of the Weaver-Helmberger comment concerns the absence of commercial stocks. They imply that the existence of private speculation may preclude the government from operating quantity stabilization schemes. Including commercial stocks in our analysis does not affect the abstract measures of benefits to producers, consumers, and society from the different stabilization schemes that were analyzed. They are correct in arguing that the existence of commercial stocks will affect the budgetary aspects of different stabilizing schemes. As will be shown, this implies a transfer of income between government and speculators. In some cases, private speculation would hamper though not necessarily preclude a quantity stabilization scheme.

Following Working, Brennan, and, more recently, Peck, we specify the relevant portion of the supply of storage function as

$$M_t = \gamma(P^* - P_t) \text{ for } \gamma \geq 0, \tag{1}$$

where M_t is commercial demand for (supply of) speculative stocks at time t, P^* is expected price, and P_t is current price at time t. This relation shows that, as the expected price rises relative to current price, commercial demand for speculative inventory increases. (We abstract from pipeline or convenience stocks required for commerce.) If current price exceeds expected price, M_t becomes negative and can be viewed as a current supply of speculative stocks out of private storage. But in the rational price expectation context, current prices are unbiased estimates of the equilibrium expected price. Therefore, the expected level of commercial demand for (supply of) speculative stocks is zero. Since the equilibrium expected price is known, equation (1) says that speculators take advantage of unanticipated differences that occur between current and equilibrium expected prices as the result of various random shocks.

Since the expected commercial demand for speculative stocks is zero, the expected equilibrium prices and quantities are not affected by their inclusion. Therefore, the expected benefits to consumers and producers from various stabilization schemes are not affected by including speculators in the analysis.

Demand Stabilization

The existence of speculators affects the cost of government of the stabilization schemes. Consider the basic model stated in equation (1) of the original article. The rational price expectation approach implies

$$P^* = \frac{\alpha_0 - \beta_0}{\alpha_1 + \beta_1}. \tag{2}$$

The change in government stocks when demand is stabilized is given by

$$\Delta G(D_s)_t = S(D_s)_t - D_s - M(D_s)_t, \tag{3}$$

where $S(D_s)_t$ is given by equation (14) in the original article and D_s by equation (13). When demand is stabilized, the speculative holdings of stocks are

$$M(D_s)_t = \gamma(P^* - P(D_s)_t) = -\frac{\gamma}{\alpha_1} u_t. \tag{4}$$

The change in government stocks is

Abraham Subotnik is with the Faculty of Industrial and Management Engineering, Technion-Israel Institute of Technology, Haifa, Israel, and James P. Houck is with the Department of Agricultural and Applied Economics, University of Minnesota.

$$\Delta G(D_s) = v_t + \frac{\gamma}{\alpha_1} u_t, \tag{5}$$

compared with only v_t without speculation. Consider the expected speculative profits when demand is stabilized. These expected profits are

$$E\,\Pi(D_s) = E\{(P^* - P(D_s)_t)(PS(D_s)_t)\} = \frac{\gamma}{\alpha_1^2}\sigma_u^2, \tag{6}$$

where $(D_s)_t$ is speculative profits at time t when government stabilizes demand. Letting $R(D_s)$ be the expected government deficit when demand is stabilized, it can be shown that

$$R(D_s) = \frac{\gamma}{\alpha_1^2}\sigma_u^2. \tag{7}$$

The original analysis of this case showed that, when demand was stabilized and no speculation existed ($\gamma = 0$), the scheme was neutral in its budgetary aspects. When speculation is allowed, the government runs a deficit that is actually a transfer payment to speculators. If only the supply function is unstable in this case, there are no gains to speculators and no extra costs to government.

Incidentally, the storage capacity needed by speculators to handle 95% of all possible cases is $1.96(\gamma/\alpha_1)\,\sigma_u$ if the random elements are normally distributed.

Supply Stabilization

The change in government stocks when supply is stabilized is given by

$$\Delta G(S_s)_t = S(S_s)_t - D(S_s)_t - M(S_s)_t, \tag{8}$$

where $S(S_s)_t$ and $D(S_s)_t$ are given by equation (21) in the original article. The commercial holding of stocks when supply is stabilized is

$$M(S_s)_t = \gamma(P^* - P(S_s)_t) = \frac{\gamma}{\beta_1} v_t. \tag{9}$$

It follows from equations (8) and (9) that

$$\Delta G(S_s)_t = \left[1 - \frac{(\alpha_1 + \gamma)}{\beta_1}\right] v_t + u_t. \tag{10}$$

The expected gains of the speculators when government stabilizes supply are

$$E\,\Pi(S_s) = E\{(P^* - P(S_s)_t)(PS(S_s)_t)\} = \frac{\gamma}{\beta_1^2}\sigma_v^2. \tag{11}$$

Letting $R(S_s)$ be the expected government deficit when supply is stabilized,

$$R(S_s) = \frac{\alpha_1 + \gamma - \beta_1}{\beta_1^2}\sigma_v^2. \tag{12}$$

Compare this result with that obtained when no speculation was assumed. If $(\alpha_1 + \gamma) > \beta_1$, the expected government deficit is larger by $\frac{\gamma}{\beta_1^2}\sigma_v^2$. On the other hand, if $(\alpha_1 + \gamma) < \beta_1$, the government surplus is smaller by the same amount. Clearly, if only demand is unstable, the expected change in the government deficit is zero whether speculation is present or not.

Assuming that the random elements are normally distributed, the size of storage capacity needed by speculators to handle 95% of all possible cases is $1.96\frac{\gamma}{\beta_1}\sigma_v$.

In conclusion, speculative profits are equal to the increased cost to the government when speculation exists. From the social point of view, these increased costs are transfer payments from taxpayers to speculators and, in principle, are recoverable.

A general analysis shows that some of the time the government would be working against the private trade in pursuit of a simple quantity stabilization goal. Sometimes both would be working in the same direction. That surely is nothing new. But in the presence of private speculation on a large or potentially large scale, a reformulation of the quantity target considering both current consumption and inventory demand surely would be sensible.

Institutional Affiliation of Authors of Contributions in Agricultural Economics, 1968–72

James Opaluch and Richard E. Just

Holland and Redman provide a survey of the affiliation of authors contributing to this *Journal* (*AJAE*), arguing that "*AJAE* contributions . . . represent one of several important indicators of departmental quality" (p. 784). In a later comment, Finley pursued their approach but argued that the Holland and Redman accounting does not allow for variation in departmental size. In other words, a smaller department may publish less than a larger department but still publish more per member.

In this note, two additional factors are considered in measuring departmental productivity of refereed published research.[1] These two considerations relate to Finley's method of computing output per member without regard to graduate student or professional status and to the agricultural economics research that is published in journals other than the *Journal*.

In the *Handbook-Directory* data Finley used to measure departmental size, graduate student and extension components of membership are highly variable among departments. In other words, if a large percentage of graduate students are members of the American Agricultural Economics Association (AAEA), a small department may appear as a relatively large one. Hence, to hold the same relative rankings, graduate students would have to publish at the same rate as faculty. In effect, Finley's method penalizes those departments that are successful in generating AAEA membership interest among their students (assuming faculty is more prolific than graduate students).[2]

Hence, the 1972 *Handbook-Directory* was used to determine whether each member was a part of the department's teaching-research faculty or was primarily of graduate student status. Since those with extension appointments may not be expected to produce refereed published research, a separate accounting was also made for those primarily involved in extension.[3] Nonstudent U.S. Department of Agriculture personnel are considered along with teaching-research faculty, since they likely contribute to the *Journal* more than graduate students. For those few members for whom the 1972 directory did not include status, the 1966 *Handbook of the American Farm Economics Association* was consulted. Student membership in 1966 was assumed to imply faculty status by 1972; otherwise, if the 1972 status was unknown, the individual was included in the graduate student total. Although this measure of departmental size is still far from perfect, the totals should now be much more reflective of the number of persons holding positions in which refereed published research is expected.

The revision in departmental size measures is evident in table 1. Considerable changes in size are implied when only teaching-research faculty is considered as well as when extension staff is included. Apparently, the earlier membership figures were somewhat misleading in terms of faculty size. For example, Finley's calculations show forty-two AAEA members at the University of California—Berkeley and forty-six at University of California—Davis in 1972, implying nearly the same departmental size. Further investigation, however, indicates that there were fourteen teaching-research faculty members at Berkeley and twenty-six teaching-research faculty at Davis or nearly twice as many at Davis as at Berkeley. The difference with Finley's figures is due to the fact that the smaller department had greater membership among graduate students, not only relatively but also absolutely.

Using the new departmental size measures, the deflated or per person published output in the *Journal* is given in table 2.[4] Since it was not possible to

James Opaluch is a research assistant and Richard E. Just is an assistant professor of agricultural and resource economics, University of California, Berkeley.

Giannini Foundation Paper No. 434.

[1] Departmental productivity includes other forms of research than refereed publications, e.g., seminars, symposia, congressional publications, etc. However, refereed journal articles usually grow out of the most original and creative papers of other types and, as such, are a better measure of quality research.

[2] Finley admits this possibility but argues that graduate student membership will probably influence its effort to publish. However, the causal effect in this relationship may well run in the other direction. Furthermore, graduate students are not likely to publish as much as teaching-research faculty, and what publications they have may be the result of teaching-research faculty stimulation. A second criticism that can be leveled against both Finley and the current study is that membership lists may be incomplete for many departments, but the extent to which this is true would be very difficult to determine.

[3] Although it would also be desirable to make a separate accounting for those with primarily teaching duties or to take account of the percentage of faculty time devoted to teaching, sufficient data are not available in the *Handbook-Directory*.

[4] Publications by graduate students are not excluded from the revised results because there were few such publications, and

determine (from the *Handbook-Directory*) the percentage of faculty time devoted to extension in departments where most faculty have split extension-teaching or extension-research appointments, published output per member is reported both with and without those listed as primarily involved in extension. The former may yield a better ranking, but the latter should be more indicative of research output by those expected to produce research (at least in departments that do not have split extension appointments). Inclusion or exclusion of extension, however, makes little difference in most of the rankings that result in table 2. Whether or not ex-

most such publications are done jointly with a faculty member. Also, faculty members are often responsible for generating the creative ideas that lead to graduate student publications.

Table 2. University Affiliation of Authors Contributing Papers to the *Journal*, 1968–72

tension is included, the University of California—Berkeley still ranks first, but the gap between first and second has widened considerably as compared with Finley's results. Also, the University of California—Davis has been displaced in second place by Oregon State University or the University of Wisconsin, depending on whether extension staff is included in departmental size. All four of the above departments, however, are in the top five by either Finley's rankings or the revised rankings of this paper.

The schools that change ranking the most (from Finley's ranking) are the University of Wisconsin, the University of Minnesota, and Pennsylvania State University. Pennsylvania State University fell from third to eighth or ninth, while the University of Wisconsin jumped from fifth to second or third. The University of Minnesota moved from thirteenth to ninth or tenth. The other notable change is that more separation exists between groups of schools than with Finley's results or the earlier Holland and Redman results. In each of the earlier studies, there were three or four clearly leading schools, but the rest of the top ten or twelve departments were not far behind.[5] In the revised results, however, the University of California—Berkeley is far in the lead at 8.44 or 10.25 pages per faculty member, and the next twelve or thirteen departments are in a group mostly between 4 and 6 pages per faculty member. In addition, the published output per member is not quite so dismal as Finley's calculations indicate; top-ranked Berkeley produced about one published *Journal* paper per faculty member in the five-year period.

The second objective of this note is to include significant agricultural economics research that is published in journals other than the *Journal*. Presumably, other refereed journal research of *Journal* quality or higher would be found mostly in well-known major economic journals, with wide circulation among the economics profession in general. A reasonable, but perhaps not exhaustive, list of such journals includes *American Economic Review, Econometrica, Journal of Political Economy, International Economic Review, The Economic Journal, The Quarterly Journal of Economics, The Review of Economics and Statistics, The Review of Economic Studies, Journal of the American Statistical Association, European Economic Review, Economica,* and *Journal of Economic Theory*.[6] Using these journals, the number of pages authored by AAEA members for the years 1968–72 was determined by using the 1972 *Handbook-Directory* (table 3).[7] Again, only those schools considered in the earlier studies by Holland and Redman and by Finley are included in table 3.[8]

[5] Only those schools considered in the earlier studies are included in table 2. On a per person basis, some schools not considered in the original study by Holland and Redman also become important. For example, the University of Chicago (which has few faculty AAEA members) would rank just behind the University of California—Berkeley in pages per faculty member with 9.13. Stanford University would rank just behind Cornell University with 3.28 and Montana State University behind Texas A&M University with 2.15.

[6] Of course, it would be interesting to consider all journals, particularly the regional agricultural economics journals. Such an exhaustive survey, however, would be very time consuming. This note is merely intended to include published research of at least the same quality as considered by the earlier surveys and admittedly is somewhat imperfect in accomplishing that objective. At least, the above list of journals should give a useful indication of the extent to which other outlets are used.

[7] Again, errors due to consideration of only those agricultural economists carrying AAEA membership must be considered. If a non-AAEA member of an agricultural economics department has written in the economic journals considered, that publication would not be considered. In the case of the University of California—Berkeley, for example, the complete total was 143.0 pages rather than 62.66, but the excess 80.34 pages could not be counted because the authors did not carry AAEA membership while in the University of California—Berkeley Department of Agricultural Economics. On the other hand, the pages of publication counted for a particular membership group more nearly pertain to that group than in Finley's and the *Journal* account in table 2. In the *Journal* account, inclusion of many *Journal* pages not authored by AAEA members could severely bias some of the pages-per-member estimates.

[8] One might question at this point why agricultural economics

As one can see, the results do not correspond closely to *Journal* output. Again, the University of California—Berkeley ranked first with nearly four times as much per teaching-research faculty member as any other department. The University of California—Davis also ranked high in publications in major economic journals, just as it did in the *Journal* publication. But the rest of the top five contributors to major economic journals ranked much lower by the earlier surveys considering only the *Journal*. Holland and Redman ranked the University of Minnesota eighth, the University of Florida eighteenth, and Oklahoma State University fourteenth. Finley ranked the University of Minnesota thirteenth, the University of Florida twentieth, and Oklahoma State University eleventh.

[*Received August 1976, revision accepted November 1976.*]

research from, say, Harvard University and the University of Chicago, is not considered. Actually, when a similar accounting was attempted for other schools as well, it was found that the results were somewhat misleading. Many of the faculty from these schools are individuals who publish extensively but apparently do not carry a primary interest in agricultural economics.

Publications

Books Reviewed

Bender, Filmore E., Amihud Kramer, and Gerald Kahan. *Systems Analysis for the Food Industry.* Westport, Conn.: AVI Publishing Co., 1976, ix + 468 pp., $45.00, $23.00 softback.

The primary audience for this book are the professional systems analysts working with firms in the food industry, but firm managers and students will also be given useful insights into the application of operations research methods to problems in the food industry. The chapters cover a wide range of techniques that have application in the food industry, and most of the book is devoted to numerical illustrations of these techniques. The principal contribution of the book is to give the reader an understanding of possible applications of the techniques discussed. For this reason, it should be read by systems analysts in the food industry and can be used to supplement undergraduate courses dealing with operations research techniques.

There are three chapters on linear programming, one on integer programming, and one on the transportation problem. These techniques are more thoroughly developed than are others. One chapter is devoted to response surface techniques (regression analysis, analysis of variance, and evolutionary operations) and another to techniques for production control (assignment and sequencing problems using techniques from industrial engineering). The chapter on inventory control and budgeting presents some good applications for planning, where the firm faces various situations with respect to demand for its products. The chapter on breakeven analysis gives the reader a better idea about the versatility of that technique and potential applications than this reviewer has seen in other books. Applications of PERT (project evaluation and review technique) and CPM (critical path method) techniques to research and development management are illustrated. The authors correctly stress the importance of accurate sales forecasting and its relation to planning for other operations in the firm. Several techniques for sales forecasting are described (Delphi, regression analysis, exponential smoothing, and time series), but most of these are not developed to the point that the reader acquires the background to apply them to a problem. The chapter on game theory exposes the reader to the concepts involved but is otherwise not very useful. Given the emphasis on linear programming, it is disappointing that the author did not use it to show its application to the solution of games with mixed strategies.

This book is a survey of techniques applicable to solution of problems in the food industry, mainly in food processing. The level of math and statistics required to comprehend most of the content is quite low, consisting of algebra and a beginning course in statistics, although this varies among chapters. Calculus is used in a few parts. Each chapter starts with simple applications and proceeds to the more complex. The reader with little or no quantitative background can grasp and work through most of the material presented.

The principal shortcoming of the book is that it lays little theoretical or conceptual foundation for the techniques described or for the interpretation of results. The authors move directly into a technique with examples in a cookbook fashion. Further, some of the data problems and limitations of techniques are not adequately treated. For example, breakeven analysis starts with a statement of fixed and variable costs, with no mention of the fact that most cost items fall between these two extremes or suggestions about how to deal with such cases. The assumptions and limitations of breakeven analysis (and other techniques) are not adequately discussed. If decisions are based on results of techniques for which the limitations are not fully understood, this could give rise to some serious problems.

Donald, Gordon. *Credit for Small Farmers in Developing Countries.* Boulder, Col.: Westview Press, 1976, xi + 286 pp., $20.00.

Perhaps there has not been such a ubiquitous set of programs for small farmer development in the third world than those of agricultural credit. Some have met with considerable success; many have been disappointing in terms of effectively and efficiently delivering credit to small farmers through viable institutional structures. Donald properly concludes, "there is much to be learned about small farmer credit," (p. 271) and, "There is a great deal that can be done to improve the effectiveness of credit in rural development, both in the adoption of relatively familiar policies within the framework of national development strategies and in experimentation with less familiar policies" (p. 271).

Within this context this volume provides a unique opportunity for both the scholar and the practitioner to understand better the wide scope of issues, problems, and strategies involved in directing credit to the small farmer. The reason is the rich source of expertise and practical experience that the author has at his disposal in the more than sixty papers dealing with credit experience in specific less developed countries and the twenty analytical papers that together comprised the 1972–73 Agency

for International Development (AID) "Spring Review" on credit programs. This volume is the author's synthesis, analysis, and extension of the materials presented at the Review. Rarely does an author have the opportunity to draw upon such a sum total of recent experience and fresh thinking as is contained in these papers and, moreover, to participate in the intensive discussions among the practitioners and experts who attended the regional workshops and final conference that comprised the Review. The result is a volume that not only views the old, long recognized but still ever-present credit problems but also presents new perspectives and insights into the nature of the problems, as well as offering new alternatives for credit policy. Properly, Donald has concentrated on the broad analysis of problems and policy strategies. He very effectively, however, places them in the context of the real world by a measured interjection of the experiences in the individual countries.

The book is logically organized. After answering the question of "why small farmer credit?" in the introduction, the remaining four sections address the role of credit, financial institutions and policies, related institutions, and policies and strategies. A slight problem occurs as Donald, in an attempt to be loyal to the authors of the original papers, does not present a completely fused and unified piece but rather one that has some degree of fragmentation that could create a problem for the nonspecialist reader.

Although the present volume—as the Review—is underwritten by AID, it is far from being a forum to justify the AID credit program position. In fact, implicit criticism of that organization's credit program policy appears in the book along with suggested alternatives that are sometimes inimical to contemporary AID policy. An example is the criticism of a standard AID credit component—the concessionary interest rate. Donald properly puts this into the context of the overall rural financial market and demonstrates how this policy works against lender profitability, tends to direct credit to larger farmers, and discourages rural savings and hence institutional capital formation. Yet, he also stresses that, since this policy is a powerful political weapon to gain small farmer favor, and given that it is widely employed, even if government leaders and policy makers could be convinced of the desirability of raising interest rates it would be very difficult to convince them that they should in fact do so.

Donald clearly leaves the reader with the sobering impression that credit programs are not the simple route to rural development as they were once imagined. Thus, he does not argue for a canned credit program strategy that can be readily transferred from country to country around the world. Rather, he argues that credit programs must be carefully tailor-made to the specific needs and conditions of a particular country or even regions within a country. Their success in part depends upon how they properly mesh with the culture of the lender and borrower and the presence of complementary programs of marketing, education, and farmer organizations. Moreover, it must be recognized that there are inherent conflicts within programs; they cannot simultaneously be expected to be low cost, have low default rates, increase production, and improve rural income distribution. Donald also suggests that more study be made of the informal market. Much can be learned from these lenders. Although interest rates are often high, these lenders offer the farmer opportune credit with an amazing degree of efficiency.

In conclusion, this volume represents a significant contribution to the credit literature because it has brought together under one cover in a readily accessible and diffusible form a balanced view of the current state of thinking about small farmer credit problems, programs, and strategies. As such, it should be a basic reference for not only the scholar but also the practitioner who is involved in designing credit programs and policy.

Fallenbuchl, Zbigniew M., ed. *Economic Development in the Soviet Union and Eastern Europe, Volume 2: Sectoral Analysis*. New York, Washington, London: Praeger Publishers, 1976, 412 + xvii pp., $27.50.

Volume 2 is said to be the third of an eight-volume set of selected papers to be published out of a total of 250 that were presented at the First International Slavic Conference in Banff, Alberta, Canada, 4–7 September 1974. Papers included in volume 2 are divided into three parts: part I, industry and foreign trade, including six papers plus comments; part II, agriculture, with seven papers, and part III, conflict in the public sector, with three papers and an introduction. Thus, the volume represents a rather heterogeneous collection of topics whose common denominator is economic development in a territory inhabited by mostly Slavic peoples and now largely under Communist rule.

The readers of this *Journal* are most likely interested in part II, agriculture. Consequently, this review focuses essentially on that part of the book, which represents a little over one-third of the total pages. The seven authors include internationally known specialists in Soviet agriculture, whose papers are essentially empirical analyses or historical reviews.

Keith Bush (Radio Liberty, Munich, Germany) in the longest and thoroughly researched lead paper of part II presents a detailed and comprehensive account of the last ten years of Soviet agriculture under the Brezhnev-Kosygin management. "Official Soviet data are utilized, despite their known

shortcomings," (p. 157) to construct a mosaic picture of inputs, supplies, policy and organizational measures, and the output levels attained. In author's summary assessment, the period represents "a consistent policy consistently implemented" (p. 157), characterized by vigorous intensification efforts in farm production to secure self-sufficiency in staple foodstuffs and in agricultural raw materials. Also, new management has sought to "correct a third of the century's exploitation and neglect of the farm sector with a massive transfer of resources from the rest of the economy" (p. 157).

Yet, as the author correctly points out, the achievements must be considered incommensurately modest due partly to unfavorable climate "but also in large part to continuing penchant for the overcentralization of decision-making and for gigantic production units, to an ideological bias against the farmer" (p. 158).

In scope, detail, and depth (196 footnote references), Bush's forty-eight-page contribution is easily the backbone of part II and of the book. It is refreshingly informative and updates developments until the year 1974. One detail in particular catches the eye because it is rarely discussed in Soviet and western publications. It concerns agricultural subsidies and the total support bill in the Soviet Union, about which very little is known, yet which happens to be the largest in the world (p. 173). Bush puts its magnitude in a glaring perspective by the following figures. The best western estimates calculated the subsidies for 1974 at some 16 billion rubles, compared to the overt Soviet defense appropriation of 17.6 billion rubles. The subsidy bill is "equivalent to over 25 percent of the national income originating in agriculture, and it is equal to about five percent of the national income (Soviet concept)" (p. 174).

The paper also shows how hazardous it is to predict in Soviet agriculture. The author thought in 1974 "that the output levels attained in the period 1971–75 will come credibly close to meeting the targets" (p. 162). The calamitous crop failure in 1975 frustrated that prediction. Although the 1971–75 overall achievement was better than the previous 1966–70 five-year period, it fell short of the 20% to 22% growth target. The judicious assessment that "the meat product targets for 1975 look unrealistically high" (p. 180) proved ironically wrong, too, because of the extra heavy slaughterings due to crop failure. Meat shortages were being felt in 1976, while in late 1975 meat supply was abundant.

In other papers, Arkadus Kahan (University of Chicago) deals with the problem of the Soviet "agrarian-industrial complexes," as yet a poorly defined and hazy concept and goal. However, it is widely discussed in connection with the grand resettlement plans for rural population into agrotowns. David M. Schoonover's (U.S. Department of Agriculture) paper outlines projections and policies of the Soviet feed-livestock economy, where the Soviets face a choice between limiting the growth of demand for livestock products and importing needed feed grain. Roy D. Laird (University of Kansas) considers Soviet farmer productivity in 1950–70 as measured by a U.S. barometer. He attempts to quantify the well-known large differences between the Soviet Union and the United States and to show the comparative advances over two decades in terms of grain per farmer, crop yields, and production per capita and per farmer. Alec Nove (University of Glasgow) continues the comparative theme with a paper on "Agricultural Performance Compared: Belorussia and Eastern Poland." It is an interesting attempt to juxtapose the performance of collectivized and peasant agriculture under nearly similar conditions, both relatively backward regions in their respective countries.

Everett M. Jacobs's (University of Sheffield) paper on the organization and management of agriculture in eastern Europe, 1967–74, reviews the reforms and new directions that have been so prominent over the last decade. A related paper by Lewis A. Fisher (McGill University) explores the efficiency in Hungarian agriculture after six years of economic reforms, which concludes part II of the book.

All the papers in part II are expertly written and informative, exploring new aspects and updating information up to 1974. The same can be said about the rest of the volume that could not be discussed here. The book is a valuable contribution to the knowledge in development problems in centrally planned command economies. It can be highly recommended to those interested in, or working on, the Soviet or East European problems.

Elmar Jarvesoo
University of Massachusetts, Amherst

Yotopoulos, Panos A., and Jeffrey B. Nugent. *Economics of Development—Empirical Investigations*. New York: Harper & Row, Publishers, 1976, xxiii + 478 pp., price unknown.

The launching pad for this book is a rude attack on the existing body of literature on development economics. In a search for how-to-do-it recipes, development economists have proliferated a variety of dogmas and abstract theories that have rarely been corroborated by hard empirical evidence. Furthermore, development economics has been enslaved to the neoclassical paradigm with its emphasis on smooth, continuous, and self-equilibrating growth processes. This enslavement results in total failure to predict the chronic problems of

unemployment and inequality that are so rampant in the developing world today.

The spirit of the book is of a science-to-the-rescue operation. By sifting out those theories and hypotheses that have, or can be, empirically tested and verified, it is hoped to provide the building blocks for an eventual general theory of economic development. Special features of the rescue operation are an eclectic approach to avoid the pitfalls of dogma and fundamentalism and the consideration of models of structural disequilibria to account for such phenomena as chronic unemployment and poverty.

After a brief review of the method of scientific investigation, a number of historical and socioeconomic theories of development are quickly dismissed (e.g., Rostow and Adelman and Morris) as being inoperational in terms of empirical testing. The book then proceeds to a lengthy review of many bits and pieces of neoclassical analysis. Herein is to be found a solid treatment of the microeconomics of production and especially of the definition and measurement of economic efficiency in resource use. The latter suffers somewhat from an excessive concentration on single-product models for statistical testing. A growing literature on allocative behavior as studied through mathematical programming models has been totally ignored, despite its richer behavioral and technical content. One can only be awed, too, by the esoteric derivation of an index of economic rationality (pp. 88–92 and chapter appendix) that collapses to the essential proposition that firms operating on Cobb-Douglas production functions differing only by a constant term will combine their inputs in directly proportional ways.

The book proceeds to a discussion of the efficiency costs of monopoly and trade distortions, suggesting that these costs may have been underestimated in the past because of the limitations of partial equilibrium analysis. A section on dynamics then provides a useful review of such topics as adaptive learning behavior in supply response models, the sources and measurement of technological change, models of savings behavior, and human capital theory.

The book reverts to a key theme that economic development involves structural shifts and changes and that growth is a process of successive disequilibria rather than of smooth, neoclassical change. Some evidence on migration and urban-rural wage differentials is then mustered to challenge the validity of the neoclassical paradigm that predicts that migration acts to equalize earnings. A rather unsatisfactory review follows of some economic models that possibly explain continued rural-urban migration despite prevalent urban unemployment. Likewise, a chapter on income distribution, poverty, and dualism follows, which, while highlighting the shortcomings of the neoclassical paradigm, fails to provide anything very useful in the way of disequilibria hypotheses. There is a useful review of alternative measures of income distribution and of some statistical analysis that relates various socioeconomic variables to income inequality, but little is offered in the way of a theory of poverty.

This rather vacuous treatment of development disequilibria fizzles out with a covert return to equilibrium analysis. There follow review chapters on the interactions between agriculture and nonagriculture, on the sectoral composition of growth (including a discussion of balanced versus unbalanced growth), and on the advantages and disadvantages of trade and economic integration. The usual tools of input-output models and partial equilibrium analysis figure prominently in these discussions.

Finally, under the heading of development disquilibrium—planning, there is a review of project appraisal techniques and a rather dated introduction to macroeconomic planning models for consistency evaluation and normative planning.

The authors are right to stress the need for a theory of development disequilibria. This, of course, is not entirely a new departure—witness the large Marxian literature on the subject. The problem faced by the authors is that they have set up stringent standards for empirical verification of any hypothesis that they are willing to accept, and existing theories on development disequilibria simply cannot be reduced to neat mathematical propositions for statistical evaluation. One admires the authors' belief that development economics should, and can, be reduced to an exact science. However, if the content of this book is any indication of the likely content of that science, then this reader for one has grave doubts about its value in contributing to the mastering of the diverse political, historical, social, and economic forces that impinge upon the development process.

The book is not without its merits, however. It is a useful review of many diverse topics in applied econometrics that have relevance to development economics. As such, it should prove useful to graduate students, teachers, and researchers alike. The treatment is largely mathematical; despite claims to the contrary, the book will probably be of little value to readers without a good quantitative training.

Regrettably, the style of the book is often pretentious and irritating. In exaggerating the authors' own contributions to the literature, the book loses much in the way of a balanced review. There is also a generous share of errors and model misspecifications for those who care to work through the algebra. For example, the proposed statistical estimation of the matrix BB^{-1} $(= I)$ on page 33 can only be described as quaint, whereas the definition of the ijth element of $(I - A)^{-1}$ as $1/(1 - a_{ij})$ on page 267 is

Announcements

Annual Meeting, 1977

The annual meeting of the American Agricultural Economics Association will be held jointly with the Western Agricultural Economics Association at the Town and Country Motel, San Diego, California, 31 July–3 August. Inquiries should be directed to Kenneth R. Farrell, President, AAEA, or William E. Martin, President, WAEA.

Editor-Elect

Starting with the February 1978 issue, V. James Rhodes will be the editor and S. R. Johnson the associate editor of this *Journal*. An announcement about the Book Review Editor will be made in the August issue. Starting 27 June, new submissions of manuscripts should be sent to V. James Rhodes, Department of Agricultural Economics, 200 Mumford Hall, University of Missouri, Columbia, Missouri 65201. Revisions of prior submissions should be sent to the current editor at Cornell so that the entire folder may be forwarded to the new editor.

NACTA Meets

The National Association of Colleges and Teachers of Agriculture will hold its annual conference 13–15 June 1977. The meeting will be held on the campus of The Pennsylvania State University at University Park. The theme of this year's conference is "Effective Teaching in Agriculture: By All Means." For information on this meeting, write to Robert E. Swope, 217 Agricultural Administration Building, University Park, Pennsylvania 16802.

Employment Service

Employment services will be provided at the AAEA annual meeting in San Diego, 31 July to 3 August 1977. These services are an extension of the year-round service provided by the AAEA's Registry for Agricultural Economists. Since the Registry provides year-round service, persons should register as soon as they become available for a job assignment, whether for a temporary or a long-term assignment. As previously announced, those persons who intend to use the employment service at the San Diego meeting and who wish to have their resumes sent to employers prior to the meeting should be registered by 1 June 1977. Employers who wish to receive resumes prior to the meeting should have their job vacancies listed by 1 July 1977. Registration forms may be obtained from the Registry for Agricultural Economists, Illinois State Employment Service, 40 West Adams Street, Chicago, Illinois 60603; telephone: 312-793-4903.

AAEA Committee Structure, 1976–77

Ad Hoc Committees

AJAE Page Charge

Lee M. Day, Chairman, Cornell University
Neil E. Harl, Iowa State University
V. James Rhodes, University of Missouri
William G. Tomek, Cornell University

Edward W. Browning Award Nominations

A. Gordon Ball, Chairman, University of Guelph
Irving Dubov, University of Tennessee
Jerry B. Eckert, Colorado State University
Vernon R. Eidman, University of Minnesota
Terry F. Glover, Utah State University
Dale J. Menkhaus, University of Wyoming
Everett E. Peterson, University of Nebraska
Richard W. Schermerhorn, University of Idaho

Special Committees

Alternative Publications

Verner G. Hurt, Chairman, Mississippi State University, 1975
Harold F. Breimyer, University of Missouri, 1975

Personnel

Agricultural Development Council

Retirement: Arthur T. Mosher, former associate in Sri Lanka, is in Ithaca, New York.

University of Arizona

Appointment: Marilyn A. Altobello, formerly with the ERS, USDA, is an assistant professor.

Cornell University

Appointments: Kenneth V. Gardner, senior extension associate, is an extension land use specialist; **William King,** formerly at Purdue University, is a research support specialist in land economics and regional agricultural studies; **Michio Sugiyama,** professor, Gifu University, Japan, is a visiting fellow.
Honors: Howard E. Conklin, professor, and **Robert S. Smith,** professor of farm finance, received special citations from the New York State Association of County Agricultural Agents.

University of Florida

Appointments: Bennett Abbitt, assistant professor, is an area farm management economist at the Area Resource Economics Center, Lake Alfred; **Roy R. Carriker,** Ph.D. Virginia Polytechnic Institute and State University, and **Richard L. Kilmer,** formerly with the USDA, are assistant professors; **John R. Gordon,** formerly at Purdue University, is an associate professor; **Richard C. Hooks** is an assistant.
Leaves: Max R. Langham remains on leave with the Agricultural Development Council, Singapore, for one more year through 1977; **Cecil N. Smith** is on leave with the Development Planning and Research Associates of Manhattan, Kansas, for six months beginning 26 Jan. 1977.

University of Guelph

Appointments: Thomas F. Funk is on the Board of Directors of the Canadian Agrimarketing Association for two years; **Larry Martin** is on the Board of Governors of the Winnipeg Commodity Exchange for one year.

CED: Commodity Economics Division of the Economic Research Service; EDD: Economic Development Division of ERS; FDCD: Foreign Demand and Competition Division of ERS; NEAD: National Economic Analysis Division of ERS; NRED: Natural Resource Economics Division of ERS.

University of Illinois

Leave: Takashi Takayama is a visiting professor, University of Florida.

Louisiana State University

Appointment: Wayne M. Gauthier, Ph.D. Oklahoma State University, is an assistant professor for three years under PL 89-106 grant funds.

University of Maryland

Appointments: Allen M. Prindle, Ph.D. The Pennsylvania State University, is an assistant professor in agricultural policy; **Ivar Strand,** former assistant professor, College of William and Mary, is an assistant professor in marine resource economics.

University of Massachusetts

Leave: Bradford D. Crossmon, professor of food and resource economics, is a visiting professor, University of Arizona, for six months.

Michigan State University

Appointment: Herbert Kreisel, professor, is in Korea on an MSU project.
Returns: Kelly Harrison is back from Colombia; **Garland Wood** is back from Pakistan.

University of Minnesota

Appointments: P. C. Goswami, professor and head, Department of Agricultural Economics, Assam Agricultural University, Jorhat, India, is a visiting professor, 1 Jan.–30 June; **Jean L. Kinsey,** Ph.D. University of California, Davis, is an assistant professor in consumption-consumer economics; **Glenn L. Nelson,** formerly at Purdue University, is in the Department of Agriculture and Applied Economics.
Leaves: John D. Helmberger, professor, is on leave with Tamil Nadu Agricultural University, Coimbatore, India, 20 Dec.–1 Apr.; **Robert W. Snyder,** associate professor and extension land economist, is on sabbatical leave at the William Mitchell College of Law, 16 Nov. 1976–15 May 1977.

University of Missouri

Appointments: Patrick Cantlon, Ph.D. University of Wisconsin—Madison, is an assistant professor in extension marketing; **David E. Ervin,** Ph.D. Oregon State University, is an assistant professor in natural resources.

Ohio State University

Returns: Richard D. Duvick, associate professor, is back after two years in Korea with a cooperative project concerned with Korean agricultural policy; **Thomas T. Stout,** professor, is back after four months as a visiting professor, University of Alberta, Canada.

Pennsylvania State University

Leave: Milton C. Hallberg is a visiting professor, Oklahoma State University, through June 1977.
Retirement: George E. Brandow, former professor of agricultural policy, after 37 years of service.

Purdue University

Appointments: David A. Bessler, Jon A. Brandt, Stephen P. Erickson, Marshall A. Martin, and **Wallace E. Tyner** are assistant professors.
Leave: Otto C. Doering, Jr., is on leave with the Agricultural Policy Analysis Program Area, CED, ERS, USDA.
Resignations: Donald A. Hilger is in the Economic Analysis Department, Cargill, Inc., Minneapolis, Minnesota; **Lennis D. Mitchell** is with Fairmont Food Company, St. Louis Park, Minnesota; **William F. Newell** is an agricultural economist with the Inter-State Milk Producers, Southampton, Pennsylvania; **Robert J. Rades** is with Snyder Associate Inc., Consultants, West Lafayette, Indiana.
Honors: Otto C. Doering, Jr., received the Junior Award for an extension specialist; **Eric C. Oesterle** received the USDA tenure award for 30 years extension service to Indiana; **G. Edward Schuh** is a member and the director of the National Bureau of Economic Research.

Rutgers—The State University

Appointments: Roger Beck, Ph.D. Pennsylvania State University, is an assistant professor in environmental and business economics; **Michael Varner,** Ph.D. Cornell University, is an assistant professor in marketing research.
Resignation: Farrell E. Jensen is the director of marketing, Food Machinery Corporation.

Honor: Daymon W. Thatch received the 1976–77 Distinguished Member Award from the Northeast Agricultural Economics Council.

Texas A&M University

Appointment: Peter J. Barry, associate professor, is the editor of the *Western Agricultural Economics Journal,* 1976–79.

Texas Tech University

Appointment: Bob Davis, former associate professor, University of Houston, is an associate professor.

U.S. Department of Agriculture

Appointment: Harry Ayer, former associate professor, University of Arizona, is with the Resource Program Studies staff, NRED, Tucson, Arizona.
Appointments in CED: James D. Johnson, Ronald L. Meekhof, and **Ronald R. Miller** are with the Agricultural Policy Analysis Program Area; **R. McFall Lamm** is with the Oil Crops Program Area, Blacksburg, Virginia; **Patrick Moast** is with the Dairy Program Area; **Michael D. Weiss** is with the Forecasting Support Group.
Appointments in EDD: Thomas F. Davis, Ph.D. University of Pittsburgh, is a research economist with the Income Studies Program Area; **Linda Ghelfi** and **Shirley A. Pryor,** Ph.D. Michigan State University, are with the Income Studies Program Area; **Bernal Green** is the leader of the Health and Education Studies Program Area.
Appointments in NEAD: Robert J. Lenahan, Ph.D. Cornell University, is a consumer economics and demand analysis specialist; **William W. Lin,** formerly with Oak Ridge National Laboratory, is with the Structure and Adjustments Program Area; **Chun-lan Lee Liu,** formerly with the Illinois State Water Survey, is with the Economic Projections and Analytical Systems Program staff.
Reassignments: Stanley Daberkow, formerly with the Regional Analysis Program Area, EDD, Davis, California, is with the Manpower Studies Program, EDD; **Andrew Duymovic,** formerly with the Fruits, Vegetables, Sweeteners, and Tobacco Program Area, CED, is with the FDCD; **Frank Gomme,** formerly with the Grains and Feed Program Area, CED, is with the Office of General Sales Manager; **George Hoffman,** formerly with the Meat Animals Program Area, CED, is at the University of Min-

nesota under the Government Employees Training Act; **John E. Lee, Jr.,** former director, CED, is the director, NEAD; **John L. Okay,** former program analyst, Cooperative State Research Service, is director, Program Evaluation Division, Soil Conservation Service; **James L. Pearson,** former deputy director, CED, is the deputy director, NEAD; **Edward Rall,** formerly with the Poultry Products Program Area, CED, is with the EDD; **Ann G. Sibold** and **William A. Sinclair,** both formerly with the EDD, are with the Office of Management and Finance.

Reassignments in CED: Edward V. Jesse, formerly with the Fruits, Vegetables, Sweeteners, and Tobacco Program Area, is in Davis, California; **Mack Leath,** formerly stationed with the Grains and Feeds Program Area in Prairie Village, Kansas, is in Urbana, Illinois; **Leroy Rude,** formerly with the Grains and Feeds Program Area, Pullman, Washington, is with the Agricultural Policy Analysis Program Area; **Loyd Teigen,** formerly with the NEAD, is with the Forecasting Support Group.

Reassignments in NRED: Verel Benson, formerly with the CED, is with the Resource Studies staff, Lincoln, Nebraska; **Anthony M. Grano,** formerly in Washington, D.C., is leader of the North Central Resource Program Group East Lansing, Michigan; **James B. Johnson,** formerly with the Meat Animals Program Area, CED; **Duane Paul,** formerly with the CED, is with the Environmental Studies staff; **John Putman** is working on a project on estimating agricultural production potential in low-income countries, East Lansing, Michigan; **Harold Stults,** formerly in Denver, Colorado, is the deputy director of Resource Program Studies.

Return: Norman D. Kimball is back with the NRED, Berkeley, California, after a year in Tanzania.

Resignations: Lon Cesal, former leader, Industrial Location Program Area, EDD, is with the Technical Assistance Bureau, Agency for International Development; **Richard O. Wheeler,** formerly with the Meat Animals Program Area, CED, is the director of the Winrock International Livestock Research and Training Center, Little Rock, Arkansas.

Retirement: Olen E. Leonard, formerly with the Manpower Studies Program Area, EDD, Tucson, Arizona.

Washington State University

Appointment: H. Alan Luke, formerly with the Western Dairymen's Cooperative Association, Salt Lake City, Utah, is a professor.

Other Appointments

Donato B. Antiporta, Ph.D. University of Minnesota, is an assistant professor with the Institute of Agricultural Development Administration, University of the Philippines at Los Banos.

Andrew B. Brabrand, M.S. Virginia Polytechnic Institute and State University, is with the Virginia Department of Agriculture and Commerce.

Keith Elsberg, M.S. University of Missouri, is an economic analyst with Edwin Jaenke Associates, Washington, D.C.

Robert H. Hendricks, Ph.D. University of Missouri, is a project director of economics and marketing with the Rural Development Center, Tifton, Georgia.

James House, M.S. University of Missouri, is a commodity analyst with the Louis Dreyfus Corporation, Stanford, Connecticut.

Rolando Jiron, M.S. University of Missouri, is an economist with the Ministry of Agriculture, Managua, Nicaragua.

James E. Kocher, Ph.D. Michigan State University, is an institute associate with the Harvard Institute for International Development, Harvard University.

Roy Kramme, M.S. University of Missouri, is the head wrangler with the Lost Valley Ranch, Sedalia, Colorado.

Gerard McMahon, M.S. University of Missouri, is a research economist with the Jesuit Volunteer Corporations, Center for Science in the Public Interest, Jenkins, Kentucky.

Bekha Lal Maharajan, Ph.D. University of Missouri, is an economist with the Ministry of Agriculture, Kathmandu, Nepal.

Lewis E. Queirolo, M.S. Oregon State University, is an economic analyst with the Commercial Fisheries Entry Commission, Juneau, Alaska.

Enrique Tellez, M.S. University of Missouri, is an economist with the Ministry of Agriculture, Managua, Nicaragua.

Ph.D. Recipients by Subject

Agricultural Economics, General

James C. Cornelius, B.S. University of California, Davis, 1970; M.S. University of Wyoming, 1972; Ph.D. Washington State University, "An Economic Evaluation of the Agricultural Exemption in National Transportation: The Performance of Motor Carriers of Exempt Agricultural Commodities."

Agricultural Finance, Capital and Credit

Kamol Boondiskulchok, B.S. Indiana University, 1970; M.S. Texas A&I University, 1972; Ph.D. Texas A&M University, "Economic Analysis of Correspondent Banking as a Source of Funds to Texas Agriculture."

Gershon Feder, A.B. Tel Aviv University, Israel, 1972; Ph.D. University of California, Berkeley, "Default Risk Indicators in International Borrowing."

William F. Hampel, Jr., B.A. University of Dallas, 1972; Ph.D. Iowa State University, "A Maximum Bid-Price Model to Evaluate Factors Influencing Farmland Values."

Tran Nhu Long, Ingenieur Agronomique National Agricultural Center, Saigon, 1964; Ph.D. University of Florida, "Capital Needs in the Agriculture of South Vietnam."

Fernando Curi Peres, B.S. Federal University of Vicosa, Brazil, 1965; M.S. Federal University of Vicosa, Brazil, 1969; Ph.D. The Ohio State University, "Derived Demand for Credit Under Conditions of Risk."

Lindon Robison, B.S. Utah State University; M.S. University of Illinois; Ph.D. Texas A&M University, 1975, "Financing Agriculture in Southwest Texas—The Role of Commercial Banks."

Kenneth Eugene Stone, B.S. University of Illinois, 1958; M.M.S. Texas Christian University, 1971; Ph.D. University of Illinois, "Effects of a Variable Amortization Payment Plan on the Financial Organization of Illinois Cash-Grain Farms."

Larry A. Walker, B.S. Iowa State University, 1971; M.S. Iowa State University, 1974; Ph.D. Iowa State University, "The Determination and Analysis of Iowa Land Values."

Kenneth Neal Wegenhoft, B.S. Texas A&M University, 1967; M.S. Michigan State University, 1970; Ph.D. Oklahoma State University, 1975, "Micro Effects of Alternative Income Tax Management Strategies on Northwest Oklahoma Farms."

Agricultural Income; Rural Poverty

Gordon L. Myer, Jr., B.S. North Dakota State University, 1965; M.S. North Dakota State University, 1972; Ph.D. University of Missouri, "The Missouri Small Farm Program: An Analytical Evaluation."

Agricultural Labor; Rural Manpower

Geraldo Sant'Ana de Camargo Barros, B.S. University of Sao Paulo, Brazil, 1970; M.S. University of Sao Paulo, Brazil, 1973; Ph.D. North Carolina State University, "Asking Wages, Market Wages, and the Off-Farm Labor Supply by Farm Operators."

Stanley F. Hoppe, B.S. Michigan State University, 1966; M.B.A. Central Michigan University, 1971; Ph.D. Washington State University, "Occupational Mobility of Rural Workers."

Ronald Lance Shane, B.S. University of Nevada, 1968; M.S. University of Nevada, 1971; Ph.D. North Carolina State University, "Labor Supply of Wives and Young Family Members in the Hired Farm Work Force."

Agricultural Products: Demand, Supply, Prices

Mario M. Amin, B.S. California State Polytechnical Institute, 1970, M.S. University of Florida, 1972; Ph.D. University of Florida, "Allocations of Florida Pompom Chrysanthemums to Selected Regional Markets."

Paul Kenneth Blakeley, B.B.A. Loyola University, Chicago, 1968; M.A. McMaster University, Ontario, Canada, 1969; Ph.D. Virginia Polytechnic Institute and State University, "A Quarterly Feeder Cattle Price Forecasting Model with Application Towards the Development of a Futures Market Strategy."

Thomas James Cusack, B.S. University of London, England, 1969; M.S. University of Guelph, Canada, 1971; Ph.D. Oregon State University, "An Analysis of Demand for U.S. Winter Pears in Export Markets."

Vo Huu De, Engineer of Agriculture Saigon National Agricultural Center, 1967; Ph.D. University of Florida, 1975, "Demand for Food in South Vietnam and Projections for 1980."

Gordon T. Gemmill, B.S. London University, England, 1968; M.S.C. Reading University, England, 1969; M.A. Michigan State University, 1974; Ph.D. Michigan State University, "The World

---

The names of Ph.D. recipients are provided by departments of agricultural economics and by departments of economics with majors in agricultural economics. The list is for degrees granted in the calendar year 1976, unless otherwise noted.

Sugar Economy: Econometric Analysis of Production and Policies."

Doyle Jeon, B.A. Seoul National University, S. Korea, 1962; B.A. Kon-Kuk University, S. Korea, 1967; M.S. Kansas State University, 1971; M.B.A. Kansas State University, 1973; Ph.D. Kansas State University, "World Wheat Economy: Development of Dynamic Analysis of an Imperfect Market."

Betsey Ann E. Kuhn, B.A. Goucher College, 1970; M.A. Stanford University, 1973; Ph.D. Stanford University, "An Estimation Model for Futures Contract Margin Requirement."

Mark B. Levine, B.S. University of Missouri, 1970; M.S. Cornell University, 1973; Ph.D. Cornell University, "The Use of Information for the Price Determination of Grains for Export."

Thomas Gordon MacAulay, B.S. University of Melbourne, Australia, 1965; M.S. University of Melbourne, Australia, 1970; Ph.D. University of Guelph, Canada, "A Recursive Spatial Equilibrium Model of the North American Beef Industry for Policy Analysis."

Louis A. Pascal Mahe, Ingenieur Agronome, National School of Agricultural Sciences, Rennes, France, 1966; License es Sciences Economiques, University of Paris, France, 1968; Ph.D. University of Minnesota, "An Econometric Analysis of the Hog Cycle in France in a Simultaneous Cobweb Framework and Welfare Implications."

Sharif M. Masud, B.A. University of Dacca, Bangladesh, 1965; M.S. E. Pakistan Agriculture University, Bangladesh, 1967; M.S. University of Illinois, 1973; Ph.D. Washington State University, "A Farm Level Demand and Optimum Allocation of the Pacific Coast Bartlett Pear Industry."

Gordon Stuart Sanford, B.S. University of Connecticut, 1961; M.S. University of Connecticut, 1963; Ph.D. North Carolina State University, "Estimation of Supply and Demand Relationships for Selected Pulses on the Coast of Peru."

James N. Trapp, B.S. Kansas State University, 1969; M.S. Kansas State University, 1971; M.A. Michigan State University, 1974; Ph.D. Michigan State University, "An Econometric Simulation Model of the United States Agricultural Sector."

Stanley Der-Hsiung Wang, B.S. Taiwan Provincial Chung-Hsing University, 1964; M.S. Taiwan Provincial Chung-Hsing University, 1967; Ph.D. Oregon State University, "An Econometric Study of the Canadian Salmon Fisheries."

Abner Willis Womack, B.S. Auburn University, 1964; M.S. Auburn University, 1966; Ph.D. University of Minnesota, "Domestic Demand for U.S. Feed Grains: Corn, Sorghum, Oats and Barley, an Econometric Analysis."

Cooperatives and Cooperation

Anthony Ikpi Ettah Ikpi, B.S. University of Ibadan, Nigeria, 1970; M.S. University of Ibadan, Nigeria, 1972; Ph.D. Purdue University, "An Analysis of Management Decision Making in Agricultural Cooperatives: Some Case Studies."

Bruce L. Swanson, B.S. Ohio State University; M.S. University of California, Davis; Ph.D. Texas A&M University, 1975, "An Economic Analysis of Pre- and Post-Merger Characteristics of Agricultural Cooperative Firms and Implications for Planning, Financing and Growth."

Economic Development, Growth, and Planning

Sohrab Abizadeh, B.S. Pahlavi University, Iran, 1968; M.A. University of New Brunswick, Canada, 1973; Ph.D. Oregon State University, "Tax Components and the Degree of Economic Development."

Donato Baraquia Antiporta, B.S. University of Philippines, 1966; M.S. Indian Agricultural Research Institute, New Delhi, India, 1970; Ph.D. University of Minnesota, "The Structure of Regional Rice Production in the Philippines."

Siddanaik Bisaliah, B.A. University of Mysore, India, 1960; M.A. University of Mysore, India, 1961; Ph.D. University of Minnesota, "Effects of Technological Change on Output, Employment and Functional Income Distribution in Indian Agriculture: A Case Study of the Punjab Wheat Economy."

Peter H. Calkins, A.B. Harvard University, 1968; A.M. Harvard University, 1971; Ph.D. Cornell University, "Shiva's Trident: The Impact on Income, Employment and Nutrition of Developing Horticulture in the Trisuli Watershed, Nepal."

Seok Jung Chang, B.A. Seoul National University, S. Korea, 1965; M.E. North Carolina State University, 1973; Ph.D. North Carolina State University, "An Economic Analysis of the Adoption of New Wheat Varieties under Uncertainty in Ferogepur District."

Anna Luiza Ozorio De Almeida, B.A. San Francisco State College, 1971; Ph.D. Stanford University, "Dualistic Development in Brazil: Industrialization and Demand for Low Skill Services."

Valimohamed Jamal, B.A. Cambridge University, England, 1964; M.A. Stanford University, 1970; Ph.D. Stanford University, "The Role of Cotton and Coffee in Uganda's Economic Development."

Jung je Joe, B.A. Seoul National University, Korea, 1963; M.A. Seoul National University, Korea, 1970; M.S. Kansas State University, 1973; Ph.D. Kansas State University, "An Application of Linear Programming Models to the Growth of Korean Economy through 1981."

Dean A. Linsenmeyer, B.S. University of Nebraska, 1971; Ph.D. Michigan State University, "Economic Analysis of Alternative Development Strategies for Sierra Leone Marine Fisheries."

Bekha Lal Maharajan, B.A. Patau College, Kathmandu, Nepal, 1964; M.A. Tribhuvan University, Kathmandu, Nepal, 1965; M.S. Indian Ag-

ricultural Research Institute, New Delhi, India, 1968; Ph.D. University of Missouri, "An Evaluation of Agricultural Production Systems and Alternatives for Small Farm Areas."

Marshall A. Martin, B.S. Iowa State University, 1966; M.S. Purdue University, 1972; Ph.D. Purdue University, "The Modernization of Brazilian Agriculture: An Analysis of Unbalanced Development."

M. S. Noori-Naini, Dip. University of Tehran, Iran, 1965, Ph.D. Cornell University, "An Economic Analysis of Resource Allocation Issues in Traditional Agriculture: A Case Study of Neishaboor District of Iran, 1969–70."

A. Unal Sarigedik, Agricultural Engineer, University of Ankara, Turkey, 1964; M.S. Oklahoma State University, 1969; Ph.D. Oklahoma State University, "A Simulation Model for Analyzing Alternative Changes of the Oklahoma Economy and Projecting Economic Variables from 1967 to 1985."

Michael J. Schultheis, A.B. Gonzaga University, 1958; M.A. Gonzaga University, 1963; M.A. St. Mary's University, 1966; Ph.D. Cornell University, "Population Growth, Labor Utilization and Regional Development in Uganda."

Teotonio D. Teixeira, B.S. University Federal Vicosa, Brazil, 1967; M.S. University Federal Vicosa, Brazil, 1969; Ph.D. Purdue University, "Resource Efficiency and the Market for Family Labor: Small Farms in the Section of Northeast Brazil."

Manuel R. Villa Issa, B.S. Escuela National de Agricultura, Chapingo, Mexico, 1968; M.S. Colegio de Postgraduados, Chapingo, Mexico, 1971; Ph.D. Purdue University, "The Effect of the Labor Market on the Adoption of New Production Technology in Rural Development Projects: The Case of Plan Puebla, Mexico."

Walter Charles Walden, B.S. Mississippi State University, 1968; M.S. Mississippi State University, 1970; Ph.D. University of Florida, "An Interindustry Analysis of Technological Innovation and Regional Impact: The Case of Flue-Cured Tobacco."

Fred E. Winch, B.S. Cornell University, 1964; M.S. University of Vermont, 1968; Ph.D. Michigan State University, "Costs and Returns of Alternative Rice Production Systems in Northern Ghana: Implications for Output, Employment and Income Distribution."

Energy

Dan Dvoskin, B.S. California State Polytechnic University, 1972; Ph.D. Iowa State University, "A National Model of Energy Use in Agricultural Production."

Environmental Economics; Conservation

James A. Gibson, B.S. University of California, 1971; Ph.D. Iowa State University, "Land Use Processes and Projections: Interrelationships in Iowa Nonagricultural Land Uses."

Ardelle A. Lundeen, B.S. South Dakota State University, 1970; M.S. South Dakota State University, 1971; Ph.D. Iowa State University, "Identifying Land Use Planning Goals of Residents of Region V in Iowa."

Thomas Arnold Stucker, Jr., B.S. Purdue University, 1970; M.S. Purdue University, 1972; Ph.D. University of Illinois, "The Economic Impact of Applying Hypothetical Nonpoint Source Pollution Controls to Hog and Beef Feeding in Illinois."

Food and Consumer Economics

Jagadevappa N. Bagali, B.S. Karnatak University, India, 1956; M.S. Karnatak University, India, 1959; Ph.D. University of Florida, 1975, "Nutritional and Nonnutritional Components of Demand for Food."

Human Resource Development

James E. Kocher, B.S. Ohio State University, 1966; Ph.D. Michigan State University, "A Micro-Economic Analysis of the Determinants of Human Fertility in Rural Northeastern Tanzania."

Industrial Organization; Market Structure

David L. Barkley, B.A. Furman University, 1969; M.A. University of Georgia, 1972; Ph.D. Iowa State University, "The Factors Contributing to Industrial Outmigration from Rural Areas of Iowa."

Steve A. Halbrook, B.A. University of Arkansas, 1973; Ph.D. Iowa State University, "An Analysis of Variables Influencing the Use of the Corporate Form of Organization in American Agriculture."

Victor Kwame Nyanteng, B.S. University of Ghana, 1968; M.S. University of Ghana, 1969; Ph.D. The Ohio State University, "A Study of the Interrelationships Among Elements of Vertical Market Structure, Coordination Practices and Selected Aspects of Market Performance in the Feeder Cattle Industry."

Michael C. Varner, B.S. Pennsylvania State University, 1968; M.S. Pennsylvania State University, 1973; Ph.D. Cornell University, "Advertising and Conglomeration in the Food Processing Industries."

Institutions, Private and Public

David F. Schuy, B.S. Washington State University, 1959; M.A. Washington State University, 1963; Ph.D. Washington State University, "Criteria for the Allocation of Public Waters."

Marketing and Location

Ahmed D. Abou-Bakr, B.S. University of Heliopolis, Cairo, Egypt, 1965; M.S. University of Missouri, 1972; Ph.D. Washington State University, "The United States Sugar Position in the World Sugar Economy."

James A. Akinwumi, B.S. University of Ibadan, Nigeria, 1966; M.S. University of Ibadan, Nigeria, 1971; Ph.D. Cornell University, "Labor Productivity in Fluid Milk Processing and Packaging Operations."

Julio Arroyo Alunan, B.S. University of the Philippines, 1959; M.S. University of the Philippines, 1968; Ph.D. University of Georgia, "An Economic Analysis of the Marketing System for Cattle in the Philippines."

Arvin Ross Bunker, B.S. Arizona State University, 1970; M.S. University of Illinois, 1973; Ph.D. University of Illinois, "Impact of Rail Line Abandonment on Agricultural Production and Associated Grain Marketing and Fertilizer Supply Firms."

Ollie Ancil Cleveland, Jr., B.S. Mississippi State University, 1967; M.S. Mississippi State University, 1970; Ph.D. Oklahoma State University, "Optimum Organization of Gins and Warehouses for Marketing Cotton in the Oklahoma-Texas Plains."

Frank Arthur Dasse, B.S. University of Michigan, 1956; M.B.A. Stetson University, 1972; Ph.D. University of Florida, 1975, "Economic Impacts of Frozen Concentrated Orange Juice Futures Trading on the Florida Orange Industry."

Ernest E. Davis, B.S. Oklahoma State University; M.S. Texas A&M University; Ph.D. Texas A&M University, 1975, "An Economic Study of the Domestic Lamb Marketing Sector—An Interregional Analysis."

Edwardo Diez-Patier, B.S. E.T.S.I. Agronomos, Spain, 1971; M.S. Michigan State University, 1974; M.A. Michigan State University, 1975; Ph.D. Michigan State University, "Efficient Organization of the Fluid Milk Subsystem of Spain."

Donald O. Mitchell, B.S. Montana State University, 1969; M.S. Montana State University, 1971; Ph.D. Iowa State University, "The Level and Variability of Agricultural Exports."

Kenneth Ervin Nelson, B.A. Nebraska Wesleyan University, 1967; M.S. Oklahoma State University, 1969; Ph.D. Oklahoma State University, "A System Analysis of Information and Communication in Beef Marketing."

Alvaro Silva, B.S. Universidad Nacional de Colombia, 1967; M.S. Michigan State University, 1973; Ph.D. Michigan State University, "Evaluation of Food Market Reform: Corabastos-Bogota."

Michael T. Weber, B.S. Southern Illinois University, 1969; M.S. Michigan State University, 1970; Ph.D. Michigan State University, "An Analysis of Rural Food Distribution in Costa Rica."

Oon Lee Yeoh, B.S.A. University of Malaysia, 1966; M.S. North Carolina State University, 1968; Ph.D. University of Florida, 1975, "Welfare Gains from Supply Stabilization in the Orange Industry of Florida."

Natural Resource Economics

Roy Ronald Carriker, B.S. Eastern Illinois University, 1968; M.S. University of Illinois, 1972; Ph.D. Virginia Polytechnic Institute and State University, "Economic Incentives for Institutional Change: The Case of the Virginia Wetlands Act."

John Martin Currie, A.B. University of Manchester, England, 1966; M.A. University of Manchester, England, 1976; Ph.D. University of California, Berkeley, "Property Rights and Agricultural Land: An Examination of the Economics of Agricultural Land Tenure in England and Wales."

Donald E. Eckerman, B.A. California State University, Chico, 1972; M.S. University of California, Berkeley, 1973; Ph.D. University of California, Berkeley, "The Effects of Reservation Systems, Income, and Season on Use of California Campgrounds."

Thomas Adrian Jennings, B.A. Rice University, 1961; Ph.D. University of Florida, 1975, "A General Methodology for Analyzing Demand for Outdoor Recreation with an Application to Camping in Florida State Parks."

Jong-Ying Lee, B.S.A. National Taiwan University, 1966; M.S.A. National Taiwan University, 1969; M.S.A. University of Florida, 1972; Ph.D. University of Florida, 1975, "A Study of the Optimum Number, Sizes, and Locations of Waste Water Treatment Facilities in Alachua County, Florida."

George H. Pfeiffer, B.S. University of California, Davis, 1970; M.S. University of Wyoming, 1972; Ph.D. Washington State University, "Economic Impacts of Controlling Water Quality in an Irrigated River Basin."

Stephen Douglas Reiling, B.S. Southern Oregon College, 1967; M.S. Oregon State University, 1970; Ph.D. Oregon State University, "An Economic Analysis of Policies, Costs and Returns for Public and Commercial Campgrounds on the Oregon Coast."

John Edwin Schefter, B.S. North Dakota State University, 1975; M.S. North Dakota State University, 1968; Ph.D. Oregon State University, "The Demand for and Supply of the Characteristics of a New Residence and the Residential Location Decision."

Oliver Ray Stanton, B.S. Michigan State University, 1964; M.S. Michigan State University, 1966; Ph.D. University of California, "An Investigation of the Effect of Flooding Upon Land Value During the Transition Period from Agricultural to Urban Use and an Analysis of the Benefits Derived from Land Enhancement."

Ashton I. Veramallay, B.S. University of Wisconsin, 1970; M.S. Iowa State University, 1972; Ph.D. Iowa State University, "An Evaluation of Water Resource Developments in Guyana: With Applica-

tion to Selected Drainage and Irrigation Projects."
Gregory K. White, B.A. Vanderbilt University, 1968; M.B.A. University of Alaska, 1973; Ph.D. Washington State University, "The Impact of the Pine Bark Beetle on Recreational Values."

Production Economics and Management

Klaus F. Alt, B.S. Oregon State University, 1968; M.S. University of Illinois, 1969; Ph.D. Iowa State University, "An Economic Analysis of Field Crop Production, Insecticide Use and Soil Erosion in a Subbasin of the Iowa River."
Kenneth Ray Bolen, B.S. University of Illinois, 1962; M.S. Southern Illinois University, 1965; Ph.D. University of Illinois, "Farmer Responses to Market Uncertainty."
Lars G. Brink, M.B.A. Gothenburg School of Economics and Business Administration, Sweden, 1968; M.S. Purdue University, 1972; M.Agr. Agricultural College of Sweden, 1973; Ph.D. Purdue University, "Plans, Decisions, and Results: An Evaluation of a Procedure for Farm Planning Under Risk."
Cecil Wyman Davison, B.S. Oklahoma State University, 1964; M.S. Oklahoma State University, 1965; Ph.D. University of Illinois, "The Economic Effects on Beef Production of Feeding Young Bulls, Administering Growth Stimulants, and Crossing British Breeds."
Noel R. Devisch, Agricultural Engineer, Universiteit van Leuven, Belgium, 1967; M.S. University of Reading, United Kingdom, 1973; Ph.D. University of Missouri, "Application of the Systems Approach: An Information and Decision Model for the Hog Enterprise."
Doeke C. Faber, B.S. McGill University, Canada, 1972; Ph.D. Iowa State University, "Can Agriculture Feed the World: A World Food Analysis."
Craig V. Fulton, B.S. University of Manitoba, Canada, 1967; M.S. University of Manitoba, Canada, 1971; Ph.D. Iowa State University, "Economics of Size of Farm Machinery in Central Iowa."
William Hartley Furtan, B.S.A. University of Saskatchewan, Canada, 1971; M.S. University of Saskatchewan, Canada, 1972; Ph.D. Purdue University, "An Adaptive Economic Approach to Decision Making Under Uncertainty."
Richard Lynn Harwell, B.A. University of Texas, 1951; M.S. Texas A&M University, 1970; Ph.D. Oklahoma State University, "Economic Interaction Between Wheat and Beef in the Southern Great Plains."
Nelson Wayne Jordan, B.S. University of Florida, 1963; M.S. University of Florida, 1964; Ph.D. University of Florida, "A Quantitative Evaluation of the Economic Feasibility of Expansion in the Florida Cattle Feeding Industry."
Wallace E. Killcreas, B.S. Mississippi State University, 1964; M.S. Mississippi State University, 1966; Ph.D. Mississippi State University, "A Computerized System for Estimating the Economic Value and Growth of Natural Timber Stands in Mississippi."
Wayne A. Knoblauch, B.S. Michigan State University, 1971; M.S. Michigan State University, 1972; Ph.D. Michigan State University, "Level and Variability of Net Income for Selected Dairy Business Management Strategies."
Lynn Henry Lutgen, B.S. North Dakota State University, 1967; M.S. North Dakota State University, 1973; Ph.D. University of Nebraska, "Simulation of Crop Production—Marketing Decisions Under Uncertainty for Eastern Nebraska."
Mohammad A. Mian, B.Sc. West Pakistan Agricultural University, M.Sc. West Pakistan Agricultural University, Ph.D. University of Hawaii, "Agricultural Production Models Based on Technical Coefficients Derived from Production and Profit Functions."
Rulon Dean Pope, B.S. Brigham Young University, 1971; Ph.D. University of California, Berkeley, "An Analysis of Factors Affecting Farm Diversification: With Special Reference to San Joaquin Valley Crop Farms."
Richard A. Schoney, B.S. University of Illinois, 1964; M.S. University of Illinois, 1973; Ph.D. Purdue University, "An Economic Analysis of Selected Hay Packaging Systems under Stochastic Weather Conditions."
Dennis L. Thomas, B.S. Iowa State University, 1970; M.S. Iowa State University, 1971; Ph.D. Iowa State University, "American Agriculture in 1980 under Alternative Levels of Crop Exports and Fertilizer Usage."
Roberto Enrique Vazquez-Platero, Ingeniero Agronomo, Universidad de la Republica, Uraguay, 1971; M.S. University of Idaho, 1973; Ph.D. Texas A&M University, "Decision Models for Livestock Production in Uruguay."
David L. Watt, B.A. Graceland College, 1971; M.A. University of Missouri, 1972; Ph.D. Michigan State University, "Michigan's Agricultural Production."
Joel Sylvan Williams, B.S. Louisiana State University, 1969; M.S. Purdue University, 1972; Ph.D. University of Florida, "An Economic Analysis of Alternative Management Strategies for the Spiny Lobster Industry."
Roberto Cristian Zegers Prado, Ingeniero Agronomo, Chile, 1964; M.S. North Dakota State University, 1968; Ph.D. University of Minnesota, "Economic Analysis of Milk Production in Southern Chile."

Public Policy

Jean-Marie DeBois, Graduate University of Louvain, Belgium, 1964; M.S. University of California, Berkeley, 1971; Ph.D. University of California, Berkeley, "Policy Choice, Voting and Prisoners'

Dilemma Game, with an Application to EEC Agricultural Support."

Donald Grant Devine, B.S.A. University of Saskatchewan, Canada, 1967, M.B.A., M.A. University of Alberta, Canada, 1970, 1969; Ph.D. The Ohio State University, "An Examination of the Effects of Publishing Comparative Price Information on Price Dispersion and Consumer Satisfaction."

Robert William Jolly, B.S. University of Minnesota, 1968; M.S. University of Minnesota, 1974; Ph.D. University of Minnesota, "An Econometric Analysis of the Grain-Livestock Economy in Canada with a Special Emphasis on Commercial Agricultural Policy."

Obituary

Walter G. Miller

Walter G. Miller, economist with the Federal Highway Administration, Department of Transportation, died on 18 October 1976. Born in Jamaica, West Indies, in 1919, he worked with the Government of Jamaica in a variety of jobs in the agricultural field before migrating to the United States in 1946. His B.S. and M.S. degrees were earned from the University of California, Berkeley, where he was a four-year letterman in soccer. He received his Ph.D. in agricultural economics in 1956 from Iowa State University.

In 1956 he came to Washington, D.C., as an economist with what is now the Natural Resource Economics Division, Economic Research Service, U.S. Department of Agriculture. During his leave from the U.S. Department of Agriculture, 1962–65, he worked with the Food and Agriculture Organization of the United Nations in Rome. He returned to the ERS in 1965, working first with the Natural Resource Economics Division and later with the Economic Development Division. From 1970 to 1974, he was also a professor of economics and statistics at the Federal City College, Washington, D.C. In 1975, he transferred from the USDA to the Department of Transportation as a transportation economist and was with that department until ill health forced his retirement in July 1976.

Miller was a long-time member of the American Agricultural Economics Association, as well as the American Economics Association, Econometric Society, Western Agricultural Economics Association, and the American Statistical Association. He was elected to membership in Phi Kappa Phi and Gamma Sigma Delta, authored and coauthored numerous publications, and received an Outstanding Research Award from the American Farm Economics Association in 1960 and a Sustained Outstanding Performance Award from the USDA in 1961.

He is survived by his wife, Marion, a stepson, Darron, brothers, Harry and Albert, and an aunt, Edith Miller. Walt will be sorely missed by his many friends in the agricultural economics profession.

JOURNAL OF AGRICULTURAL ECONOMICS

Vol. XXVII, No. 3 September, 1976

CONTENTS

The Concern of Agricultural Economists in Great Britain since the 1920's ..... *K. E. Hunt*
The 'New International Economic Order' and Agricultural Economists ..... *John Ashton*
The Economics of Public Access in the Countryside ..... *K. J. Thomson and M. C. Whitby*
The 1975 E.E.C. Farm Structure Survey *D. W. Heath*
Fifty Years of Agricultural Policy ..... *M. A. Tracy*
The Political Economy of Employment Creation in Agriculture ..... *L. D. Smith*
Capital Theory and Farm Production Economics .. .. *M. Upton*
The Development of the Agricultural Economics Profession in England ..... *A. W. Coats*

Reviews, etc.

Published thrice yearly; annual subscription £5.50p
Editor: R. F. Lord, The Edinburgh School of Agriculture, West Mains Road, Edinburgh, EH9 3JG, Scotland.
Treasurer: Ian G. Reid, Department of Agricultural Economics, Wye College, Ashford, Kent, TN25 5AH, to whom all enquiries regarding membership of the Society and orders for Journals should be sent.

Financial Management

the official journal of the Financial Management Association

The FMA was formed to promote the subject of corporate financial decision-making. *Financial Management* was a natural offspring of the FMA. On a quarterly basis, *FM* brings together topics of specific interest to financial managers and others. The articles, written by financial managers and finance academicians, are functional and theoretical. The material ranges from light text to quantitative models. Emphasis is on subject matter that will contribute to both short and long run decision-making by the corporate financial manager.

Every fall, usually in October, the FMA membership participates in a three-day professional meeting. Five sessions of papers are run concurrently throughout the period. Every member is thus exposed to many papers in his particular area. For more information concerning the FMA, attending an annual meeting, and/or the possibilities of presenting a paper or acting as a discussant, contact one of the following:

Richard Bower - Editor
Dartmouth College

New memberships to:
Donald Tuttle, Executive Director
Graduate School of Business

Bloomington, Indiana 47401

Rates: $15 a year (incl. membership
Single copies - $5 per issue
Foreign postage - $2 per year

AGRICULTURAL ECONOMIST

The Agency for International Development is seeking agricultural economists for assignments abroad. Principal duties include advising foreign government leaders and their professional staffs in one or more of the following areas. Macroeconomic: economic analysis, marketing surveys, import-export studies, price structure for agricultural commodities, application of agricultural credit, design and use of statistical models. Microeconomic: involving the small farmer in studies of cost analysis, management practices, credit needs, combination of enterprises and seasonal adjustment of production. Preference will be given to applicants having some course work and practical farm experience in agronomy and animal production.

LOCATION: Africa, Asia, Latin America, and the Near East.

QUALIFICATIONS: Masters Degree in agricultural economics is required. Ph.D. is preferred. At least five years professional experience is essential. Qualifying experience includes: teaching university courses in agricultural economics, conducting research, extension work, or a combination of these or related activities. First-hand knowledge of less developed countries is highly desirable. Preference will be given to proficiency in a foreign language: French or Spanish preferred. Applicants must be U.S. citizens.

SALARY RANGE: $19,601 to $24,308 depending on qualifications and experience.

TO APPLY: Send a personal qualifications statement (SF-171) to James E. Woodhull, Recruitment Staff, Office of Personnel and Manpower, Agency for International Development, Washington, D.C. 20523.

The Agency for International Development is an Equal Opportunity Employer.

JOURNAL OF REGIONAL SCIENCE

An important new book—order your copies now at a special price

A SURVEY OF AGRICULTURAL ECONOMICS LITERATURE

Volume 1, Traditional Fields of Agricultural Economics, 1940s to 1970s

edited by Lee R. Martin, Professor of Agricultural and Applied Economics, University of Minnesota

This is the first volume of a comprehensive three-volume survey of agricultural economics literature since World War II. This volume contains surveys of the literature in seven broad areas, prepared by ten outstanding authorities.

Subjects and authors of the reviews in Volume I:

Farm Management and Production Economics, 1946-1970. Harald R. Jensen, University of Minnesota.

The Analysis of Productive Efficiency in Agricultural Marketing: Models, Methods, and Progress. Ben C. French, University of California, Davis.

Policy for Commercial Agriculture, 1945-71. George E. Brandow, Pennsylvania State University.

Postwar Policies Relating to Trade in Agricultural Products. D. Gale Johnson, University of Chicago.

Agricultural Price Analysis and Outlook. William G. Tomek and Kenneth L. Robinson, both of Cornell University.

Agricultural Finance and Capital Markets. John R. Brake, Michigan State University, and Emanuel Melichar, Division of Research and Statistics, Board of Governors of the Federal Reserve System, Washington, D.C.

Technical Change in Agriculture. Willis Peterson, University of Minnesota, and Yujiro Hayami, International Rice Research Institute, Manila, Philippines.

Published for the American Agricultural Economics Association by the University of Minnesota Press.

The regular price of Volume 1 is $25.00. Members of the American Agricultural Economics Association may order copies at a special price of $18.00 ($20.00 outside the U.S.), postpaid. This special price offer is available to AAEA members for this year only. Send your order now, using the order form below.

John C. Redman, Secretary-Treasurer
American Agricultural Economics Association
Dept. of Agricultural Economics
University of Kentucky
Lexington KY 40506

Send me _____ copies of *A Survey of Agricultural Economics Literature: Volume 1* at the special price for members of the American Agricultural Economics Association of $18.00 ($20.00 outside the U.S.), postpaid. I enclose $ _____. (Payment must accompany order.)

AGRICULTURAL ECONOMICS RESEARCH

A JOURNAL OF THE
U.S. DEPARTMENT OF AGRICULTURE
ECONOMIC RESEARCH SERVICE

APRIL 1977 VOL. 29 NO. 2

Contains articles, research notes, and book reviews on research in agricultural economics funded all or in part by USDA and cooperating agencies.

Capacity Measurement in the U.S. Agricultural and Nonagricultural Economic Sectors: A Literature Review — Heinz Spielmann

Reducing Respondent Burden for Repeated Samples — Robert Tortora

Comment on "Effects of the Exchange Rate Change on Agricultural Trade" — Maury E. Bredahl, Paul Gallagher

RESEARCH REVIEW

Agricultural-Food Policy Review — Reviewer: Allen Grommet

World Soybean Research — Reviewer: James P. Houck

The Political Economy of Natural Resources Policy — M. M. Kelso

Agricultural Production Economics in the Future — Earl O. Heady

Testing a Theoretical Model for World Trade Shares — Lloyd D. Teigen

Wheat Farmers' Demand for Commodity Loans, 1950–75 — Venkareddy Chennareddy, Lloyd I. Holmes

Cash Grain Pricing in the United States — Richard Heifner

Published quarterly

The *Canadian Journal of Agricultural Economics* is published five times yearly. The February, July, and November issues contain refereed manuscripts. The March and August issues respectively comprise the Proceedings of the Annual Workshop and the Annual Meeting. Requests for subscriptions ($20.00 annually, or membership applications (regular membership, $15.00 annually; student membership, $11.25 annually) should be addressed to The Treasurer, Canadian Agricultural Economics Society, Suite 907, 151 Slater Street, Ottawa, Ontario, Canada, K1P 5H4.

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter to the editor, the author must state (*a*) that the material has not been published, and is not being published or being considered for publication elsewhere; (*b*) that the material in the manuscript, so far as the author knows, does not infringe upon other published material protected by copyright; and (*c*) that he or she is aware that each issue of the *Journal* is copyrighted, that submission of a manuscript to the *Journal* gives the AAEA the right to publish and to copyright the material, and that republication elsewhere at a later date is contingent upon written approval from the *Journal* editor. If the applicability of point (*a*) is unclear, the author should provide an explanation of the publication status of the manuscript.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
12. **Page charge.** All published contributions, with certain specific exemptions, are subject to a charge of $40 per printed page or fraction thereof. Exemptions are granted for book reviews, papers invited by the editor, the presidential address, the fellow's lecture, and those invited addresses and papers receiving explicit written exemption from the AAEA president. If an author has no financial support from an employer or granting agency to cover the charge, an exemption may be granted. Instructions for making payment and for requesting an exemption are provided with galley proofs. If the charge is honored, 100 reprints are provided. An employer cannot request a financial exemption while agreeing to buy reprints.

American Agricultural Economics Association

President /Kenneth R. Farrell, Economic Research Service
President-Elect /R. James Hildreth, Farm Foundation
Secretary-Treasurer /John C. Redman, University of Kentucky
Past-President /James T. Bonnen, Michigan State University

Directors

Wallace Barr, Ohio State University
Richard T. Crowder, Pillsbury Co.
Sylvia Lane, University of California, Davis
Fred A. Mangum, North Carolina State University
Philip M. Raup, University of Minnesota
B. F. Stanton, Cornell University

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

The subscription rate for institutions and nonmembers is $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

Copyright © 1977 by the American Agricultural Economics Association.

An article, note, or other material appearing in the *American Journal of Agricultural Economics* may not be republished in full or in part without the express written permission of the editor.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, V. James Rhodes, Department of Agricultural Economics, Mumford Hall, University of Missouri, Columbia MO 65201.

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Herbert H. Stoevener, Department of Agricultural Economics, Oregon State University, Corvallis OR 97331.

Wendell C. Binkley, Newton Mack Penny

case of double counting—perfect collinearity, increase this cost without limit. Alternatively, imposing false restrictions while reducing variance leads to bias, and the worse the restriction, the worse the bias.[3]

In many cases, the investigator may have restrictions in mind such as pooling data, dropping variables, and so on, and he may not be certain whether the restrictions are valid. He may wish the data to reveal something about the truth or falsity of the restrictions. A common practice in such situations is to test the restrictions as a statistical hypothesis. For example, treating equation (2) as a null hypothesis about β, the Snedecor F-test calculates

$$(8) \quad u = \frac{SSE(RLS) - SSE(OLS)}{SSE(OLS)} \frac{T-k}{m},$$

where SSE(·) indicates calculated error sum of squares under either the restricted or unrestricted regressions.

If equation (2) is true, u is distributed as a central F with m and $T-k$ degrees of freedom and can be compared with tabular values for either accepting or rejecting equation (2) as a hypothesis; the outcome depends upon the significance level selected.

Thus, the heuristic notion of pretesting is not so badly placed. If the restrictions are valid, then variances can be reduced without incurring bias. The problem is that one can only test the hypothesis. There is always the chance of accepting false or rejecting true hypotheses. So when the analyst acts as if the restrictions are true (i.e., adopts $\hat{\beta}$, the restricted estimators), he runs a risk associated with type two error. If the restrictions are false, he runs a risk associated with the other type of error involved in hypothesis testing.

The pretest estimator of β based on F-testing a prior hypothesis that a set of restrictions is true is

$$(9) \quad \beta^* = \begin{cases} \hat{\beta} \text{ if } u < \lambda, \\ b \text{ if } u \geq \lambda, \end{cases}$$

where λ is a critical value from the central F and can be associated with the investigator's choice of critical value. The probability characteristics of the β^* estimator are complex. In general, the pretest estimator is biased, since $\hat{\beta}$ is biased if the restrictions are false, given that there is a nonzero probability of accepting false restrictions via the test. The characteristics of the pretest estimator are outlined in a subsequent section.

Often, hypothesis testing is not part of a pretest. The investigator may want to test for structural difference as an end product. It is only when testing leads to a choice among estimators that one is interested in the properties of β^* in equation (9).

The situation becomes even more complex when a string of restrictions are tested in sequence. Stepwise regression programs typically drop (add) a single variable at a time, sequentially screening through a batch of variables. Only a single pretest is considered in this paper, although the single test may involve simultaneous restrictions on many parameters.

Mean-Square-Error Criteria

Whether to adopt restrictions becomes a question of bias-variance trade-off. If restrictions are true, there is no issue, since the imposition of true restrictions reduces variances and does not cause bias. Imposition of false restrictions introduces bias. Thus, the only way of making a judgment on pretest estimators is to adopt either an implicit or explicit utility (or risk) function that assigns weights to bias and variance. Bancroft, in his seminal paper, gave bias tables in a two-variable case; in subsequent work he and his students often have eschewed direct adoption of a single-valued risk function, preferring to give results in a form allowing each investigator to provide his own (implicit) weights. Others have found that several nice results can be obtained by adopting some member of the class of quadratic risk functions. What follows is a brief summary of such functions.

For a scalar case, consider a parameter θ and two potential estimators, $\hat{\theta}$ and θ^*. The estimator $\hat{\theta}$ is defined to be better than θ^* in quadratic risk or MSE if

$$(10) \quad E(\hat{\theta} - \theta)^2 \leq E(\theta^* - \theta)^2.$$

The expectations above are designated MSE, since in the sampling distributions of the estimators the expressions in equation (10) are "mean" or "average" square error of the estimator from the parameter point. MSE is variance whenever the estimator is unbiased.

[3] This could be called the principle of "no free lunch" in regression analysis. For discussion of bias-variance trade-off in a two-variable model, see Wallace.

Otherwise,

$$(11) \qquad \text{MSE}(\hat{\theta}) = V(\hat{\theta}) + [\text{bias } \hat{\theta}]^2,$$

where $V(\hat{\theta})$ is the variance of $\hat{\theta}$.

Whenever a vector of random variables is being considered such as in OLS, RLS, or pretest estimators in a multiple regression model, the notion of mean square error can be generalized in different ways. For example, suppose θ, $\hat{\theta}$, and θ^* are $n \times 1$ vectors. A strong mean square error criterion requires that

$$(12) \qquad \text{MSE}(1'\hat{\theta}) \leq \text{MSE}(1'\theta^*)$$

for every $n \times 1$ vector, 1; that is, for $\hat{\theta}$ to be better in MSE than θ^*, the MSE of every linear combination for $\hat{\theta}$ must be no larger than the same linear combinations for θ^*.[4]

Criterion (12) is equivalent to the requirement that

$$(13) \quad \Sigma_{\hat{\theta}\hat{\theta}} + (\text{bias } \hat{\theta})(\text{bias } \hat{\theta})' - \Sigma_{\theta^*\theta^*} - (\text{bias } \theta^*)(\text{bias } \theta^*)' = A,$$

where A is a nonpositive definite matrix, where $\Sigma_{\hat{\theta}\hat{\theta}}$ is the $n \times n$ variance-covariance matrix for $\hat{\theta}$, bias $\hat{\theta}$ is the $n \times 1$ vector displaying bias terms for $\hat{\theta}$, and similarly for θ^*.

A weaker criterion is to require that

$$(14) \quad E(\hat{\theta} - \theta)'(\hat{\theta} - \theta) \leq E(\theta^* - \theta)'(\theta^* - \theta).$$

Criterion (14) is a direct analogue to the scalar case for MSE. The geometrical interpretation of relationship (14) is that $\hat{\theta}$ is closer, on the average, to θ in squared Euclidian distance.

The criterion in equation (14) is weaker because an equivalent requirement is for the trace of the matrix in equation (13) to be nonnegative. Thus, if $\hat{\theta}$ is better than θ^* in strong MSE, its superiority in terms of the weaker criterion is assured, but not vice versa.

No compelling reasons can be given for acceptance of all or any of the MSE criteria, except that they allow some nice analytical results to be established. Certainly, they are acceptable risk functions in the sense that bias is a "bad" and so are larger variances, but the isorisk curves thus implied are arbitrary. My impression is that part of the lack of acceptance of these or similar risk functions stems not totally from their arbitrariness but that they call attention away from best linear unbiased (BLU) estimators. Of course, the very occasions that call for MSE comparisons are those where unbiasedness is expensive in terms of variance. In a world in which data are cheaply available, BLUness should rank high, since for most estimation contexts, including linear regression, variances are reduced with additional data. For example, in a linear regression context, OLS estimators may have large variances for fixed sample size, but if more data are cheaply available, unacceptably large variances can be overcome by increasing the sample size. Unfortunately for economists, data costs usually are large, requiring in some instances a delay of a year for an additional data point. Thus, unacceptably large variances together with large expenses in obtaining more information in the form of additional sample data dictate the need for restrictions on parameters or the need for data from other sources. Whether additional information in the form of priors or other data regimes is useful can be phrased in terms of bias-variance trade-off using MSE criteria.

[4] This is analogous to the notion of generalized variance. See Toro-Vizcarrondo and Wallace for a necessary and sufficient condition that RLS be better than OLS estimators in a linear regression model.

The Pretest Estimator and Its Risk Properties

The general form of the pretest estimator discussed in this section is given in equation (9). Its characteristics depend upon the distributions of the OLS estimator b and of the RLS estimator $\hat{\beta}$, the critical value for the pretest (λ), and the distribution of the test statistic. This section includes a survey of some results in an example problem first analyzed by Bancroft, as well as results that have been established for the more general case.

The Bancroft Example: A Single Restriction

Bancroft derived expressions for the bias of a pretest estimator in the particular case of deciding whether to drop a regressor in a two-regressor model. Toro-Vizcarrondo extended the Bancroft example to derive MSE of the pretest estimator. Since the Bancroft problem includes many of the ingredients of the larger problem, it is worthwhile to review those results.

The set-up is a linear model with two regressors, X_1 and X_2, with the usual Gauss-Markov assumptions and a normally distributed error. The pretest estimator is for the coefficient of X_1, and the test is for $\beta_2 = 0$. Thus, letting β_1^* be the pretest estimator for β_1,

$$\beta_1^* = \begin{cases} \hat{\beta}_1 \text{ if } u < \lambda, \\ b_1 \text{ if } u \geq \lambda, \end{cases} \tag{15}$$

where $\hat{\beta}_1$ is the least squares estimator for β_1, dropping X_2, and b_1 is the partial regression coefficient linking X_1 to Y with X_2 in the regression. Further, λ is the critical value for the pretest of the hypothesis that $\beta_2 = 0$, and u is the square of the t-statistic usually associated with testing the hypothesis:

$$u = \frac{b_2^2}{s_{b_2}^2}, \tag{16}$$

where b_2 is the regression coefficient of X_2, and s_{b_2} is its standard error.[5]

Under the null hypothesis that the second regressor does not belong in the regression, the u-statistic is distributed as a Snedecor F with 1 and $T - 3$ degrees of freedom. However, not restricting the statistic by the null hypothesis, u is distributed as a noncentral F with 1 and $T - 3$ degrees of freedom and noncentrality parameter θ, where

$$\theta = \frac{\beta_2^2}{2V(b_2)}, \tag{17}$$

where $V(b_2)$ is the true (not estimated) regression variance of b_2. Therefore, the Bancroft set-up presents a choice of either b_1 or $\hat{\beta}_1$ as the estimator for β_1, depending upon a test outcome.

If the investigator chooses $\lambda = 0$, the OLS estimator b_1 is chosen, since the test statistic is nonnegative. The other extreme is to choose $\lambda = \infty$, insuring a choice of the restricted estimator $\hat{\beta}_1$. Therefore, the characteristics of the pretest estimator are related to the characteristics of b_1 and $\hat{\beta}_1$, being closer to those of b_1 for small λ and to those of $\hat{\beta}_1$ for large λ. Since b_1 is unbiased, its MSE is simply $V(b_1)$; $\hat{\beta}_1$ is biased unless X_1 and X_2 are uncorrelated or $\beta_2 = 0$, the bias depending upon the noncentrality parameter in equation (17). Figure 1 shows the typical shapes of MSE's for the RLS, OLS, and pretest estimators.

The shaded triangular area in figure 1 represents the potential for gain via pretest estimation. To the right of A, the OLS estimator dominates any other stepwise estimator; i.e., to the right of A for any pretest critical value λ greater than zero, the MSE of the resulting estimator is no smaller than the variance of b_1. Also, it can be shown that to the left of A the MSE of the pretest estimator is no smaller than MSE($\hat{\beta}_1$). In other words, the MSE function for the pretest estimator with λ in the open interval $(0, +\infty)$ is bounded below by the minimum of MSE($\hat{\beta}_1$) and MSE(b_1).

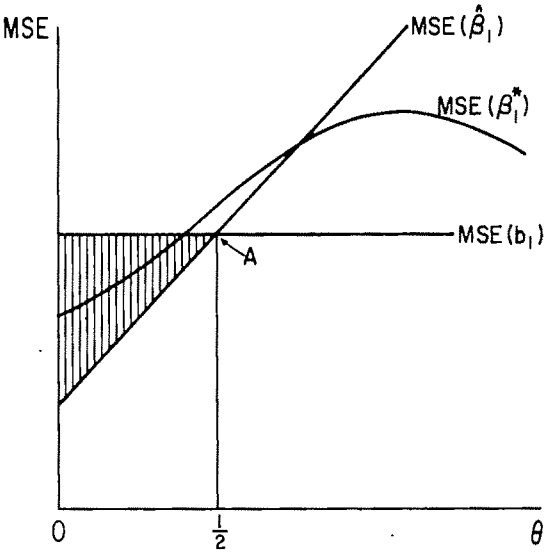

Figure 1. MSE for $\hat{\beta}_1$, b_1, and β^*_1; two-variable case

Since the pretest estimator β^*_1 is a function of three random variables $\hat{\beta}_1$, b_1, and u, the probability density of β^*_1 is the conditional density of $\hat{\beta}_1$ (given $u \leq \lambda$) times the probability that $u \leq \lambda$ plus the conditional density of b_1 given $u > \lambda$ times the probability that $u > \lambda$. Even if $\beta_2 \neq 0$, there is some probability that $u \leq \lambda$ for $\lambda > 0$, so the pretest estimator is biased in general, and the bias and variance of the pretest estimator depend upon the value of β_2, degrees of freedom (sample size), the correlation between X_1 and X_2, and λ, the critical value.

Referring the reader to Bancroft and to Toro-Vizcarrondo for the derivations, table 1 is excerpted from Toro-Vizcarrondo (pp. 60, 67).[6] As derived by Toro-Vizcarrondo, the typical shape of MSE(β_1^*) is shown in figure 1. Regression variance is taken as unity.

The following results are suggested by table 1.

(*a*) For any critical value λ, sample size, and correlation of the X's, increasing the size of

[5] The test could be, and usually is, expressed as a t rather than an F with one degree of freedom in the numerator. In making the transition from the Bancroft problem to the more complex case, it is helpful to use the F notation at this point.

[6] The biases reported by Bancroft are recomputed using modern, large-scale electronic equipment and updated algorithms for numerical intergration. Since Bancroft must have used a hand calculator to perform a tedious task, it came as a pleasurable, mild surprise that Toro-Vizcarrondo's findings to three decimal places coincided precisely with Bancroft's bias estimates.

the nuisance parameter β_2 first increases bias of β_1* and then decreases it, since if β_2 is close to zero, one tends to do the right thing (throw X_2 away), and as β_2 gets large, one tends also to do the right thing (keep X_2). The same pattern emerges for MSE for the same reason.

(*b*) As the correlation of the two regressors increases, bias and MSE increase for the pretest estimator. However, a rise in collinearity increases the MSE for both the simple and multiple regression estimators for β_1. For example, with $T = 5$ and $r_{12} = 0.8$, MSE($\hat{\beta}_1$) is 10.49, almost three times the MSE of the pretest estimator for the least favorable choice of λ.

(*c*) Lower values of the pretest critical value decrease bias, other things being equal, because low values of λ pull the risk function toward the variance of the multiple regression coefficient b_1. But for low values of β_2, lowering critical values can increase the MSE of the pretest estimators. For example, MSE for the pretest estimator is 0.365 when $\beta_2 = 0.1$, $r_{12} = 0.6$, and $\lambda = 1$, while for $\lambda = 19.51$, the comparable MSE is 0.273. For sufficiently small β_2, there is an MSE gain from excluding X_2; the greater the value of the pretest critical value, the larger the chance of keeping X_2.

(*d*) Increasing the sample size lowers MSE of the pretest, other parameters being constant. As the sample size increases, the test becomes more precise, and unless there are offsetting changes in the other parameters, it becomes more likely that the investigator will make the right decision. The power of the test increases.

The foregoing discussion no doubt leaves some questions in the mind of the reader about the nature of pretest estimators and their relationship to degrees of freedom, the pretest critical value, and the noncentrality and correlation of the regressors. However, it should be clear that trade-offs are involved and that the justification for pretesting is to accept some bias in exchange for variance reduction.

MSE Functions for Pretest Estimators with Multiple Restrictions.

The general pretest estimator β^* is chosen to be either $\hat{\beta}$, the RLS estimator, or b, the OLS

estimator, depending upon the outcome of an F-test (equation (8)). Brook (1972) investigates two different risk functions for β^*:

$$\text{(18)} \qquad \text{MSE}(\beta^*) = E(\beta^*-\beta)'(\beta^*-\beta),$$

and

$$\text{(19)} \qquad \text{MSE}(X\beta^*) = E(X\beta^*-X\beta)'(X\beta^*-X\beta) = E(\beta^*-\beta)'X'X(\beta^*-\beta).$$

Intuitively, MSE(β^*) is the mean square distance of the preliminary test estimator β^* from β, while MSE($X\beta^*$) is the mean square distance for the parameter space $E(Y|X)$ and its estimator.

Even though the researcher might have more interest in the risk characteristics for the β^* estimator, MSE(β^*) turns out to be a function of the X's, among other things. This means that Brook's findings for MSE(β^*) are conditional upon specific problem data in a way that limits the generality of his results. Alternatively, MSE($X\beta^*$) turns out to vary with the values of the regressors, but only through a well-defined parameter, and the Brook results there are more general. Therefore, the characteristics of the risk function for $X\beta^*$ are examined more thoroughly in what follows. (For other examples of scalar risk functions in a similar context, see Farebrother and Sawa and Hiromatsu.)

From Brook, the risk function for the pretest estimator of the conditional expectation of Y, given X, is

$$\text{(20)} \qquad \text{MSE}(X\beta^*) = \sigma^2\{k-m + mr(\theta, \lambda) + 2\theta[1 - 2r(\theta, \lambda) + s(\theta, \lambda)]\},$$

where

$$\text{(21)} \qquad r(\theta, \lambda) = P\left\{F'(m + 2, T - k; \theta) \geq \frac{m\lambda}{m + 2}\right\}$$

and

$$\text{(22)} \qquad s(\theta, \lambda) = P\left\{F'(m + 4, T - k; \theta) \geq \frac{m\lambda}{m + 4}\right\}.$$

The letter P denotes probability, where F' is the noncentral F density with degrees of freedom as indicated and noncentrality parameter θ. In the more general case, as opposed to the Bancroft problem examined earlier, the noncentrality parameter θ is

$$\text{(23)} \qquad \theta = \frac{(H'\beta-h)'(H'S^{-1}H)^{-1}(H'\beta-h)}{2\sigma^2}.$$

Thus, the MSE function for the pretest estimator depends upon the following parameters: (*a*) the regression variance σ^2; (*b*) the number of regressors k and the number of restrictions m; (*c*) the pretest critical value λ;[7] (*d*) the restrictions being tested and the $(X'X)^{-1}$ matrix, but all in terms of a well-defined parameter θ; and (*e*) degrees of freedom $T-k$, but through the probabilities r and s that involve the noncentral F.

Since r and s are probabilities, they are bounded by zero and one. If the pretest critical value λ is assigned either of the two extreme values, zero or infinity, the MSE function in equation (20) reduces to σ^2k and $\sigma^2[k-m + 2\theta]$, respectively, since if $\lambda = 0$, the OLS estimator is always chosen and if $\lambda = +\infty$, the RLS estimator is always chosen.[8]

Characteristics of the MSE function in equation (20) can be brought out with the aid of figure 2. (*a*) For any $\lambda \in (0, +\infty)$, MSE($X\beta^*$) $\leq$ MSE(Xb) for $\theta \leq m/4$. (*b*) The maximum of MSE($X\beta^*$) for nonzero but finite λ occurs to the right of the intersection of MSE($X\hat{\beta}$) and MSE($X\beta^*$), to the right of θ^* in figure 2.

(*c*) MSE($X\beta^*$) for $\lambda \in (0, +\infty)$ is always greater than the minimum of MSE($X\hat{\beta}$), MSE(Xb). In other words, the best that one can do in a least squares framework is to use the restrictions if the noncentrality parameter is smaller than $m/2$, where m is the number of restrictions, and to ignore the restrictions if the noncentrality is greater than $m/2$. Choosing whether to adopt the restrictions on the basis of a test leads to an estimator that is better than ordinary least squares ($0 \leq \theta < m/4$), may be better than restricted least squares ($\theta > \theta^*$), or may be worse than choosing either by some nonstochastic rule.

(*d*) For any finite choice of λ, MSE($X\beta^*$) $\to$ MSE(Xb) as $\theta \to \infty$. The common sense of this is that, if the restrictions are grossly inconsistent with the sample data, one does the right thing—reject the hypothesis that they are valid.[9] (*e*) The closer λ is to zero, the closer

---

[7] Rather than λ, the MSE function can be defined in terms of α, a significance level associated with the distribution of a test statistic under a particular null hypothesis. Given a null hypothesis and degrees of freedom, λ and α are in a one-to-one correspondence.

[8] With b being the ordinary least squares estimator, $E(Xb-X\beta)'(Xb-X\beta) = E(\epsilon'X(X'X)^{-1}X'\epsilon) = \text{tr}\, E(\epsilon\epsilon'X(X'X)^{-1}X') = \sigma^2k$. For derivation of the MSE function for the restricted least squares estimator, see Wallace (1972).

[9] One of the reviewers of this paper justifiably complained that it is difficult to get an intuitive feel for θ, the noncentrality parameter. Farebrother pointed out that, since $(H'S^{-1}H)^{-1}$ is positive definite, there exists a matrix P such that $PP' = (H'S^{-1}H)^{-1}$; hence, θ can be written as $(Q'\beta-q)'(Q'\beta-q)$, where $Q' = P'H'$ and $q = P'h$. In a specific problem setting, Q' and q can be derived, and θ is monotonically related to the sum of squares of

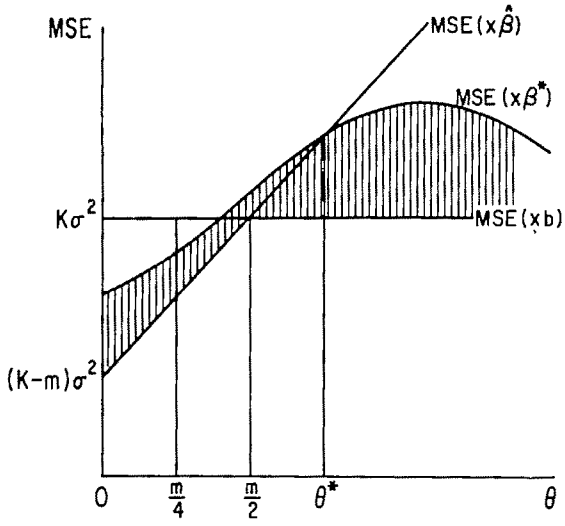

Figure 2. MSE functions for Xb, $X\hat{\beta}$, and a typical MSE function for $X\beta^*$

MSE($X\beta^*$) is to MSE(Xb). Clearly, taking λ close to zero increases the frequency of rejecting a particular hypothesis in repeated samples. So taking small λ (large rejection regions), large regret is avoided to the right of θ^*, but one gives up much chance for large gains in the region $\theta < m/2$. A completely analogous argument can be made for large λ.

The choice being discussed here is dichotomous—either ordinary least squares or restricted least squares, the choice depending upon a test outcome. If one knew the noncentrality parameter precisely, the choice would be clear. Deciding something about θ based on a random variable, in order to make a dichotomous choice of estimators, leads to the sorts of quadratic risk (MSE) properties discussed here.

One conclusion drawn by some is that, at a minimum, the investigator who pretests should choose the critical value with more care than looking it up in a 1%, 5% table. There are many different ways of choosing critical values that are "optimal," two of which are discussed in the section to follow. Various James-Stein type estimators exist that, under certain conditions, have smaller quadratic risk everywhere than the pretest estimator. There are other estimators that are random but nondichotomous, weighted functions of averages of the restricted and unrestricted least squares estimators. These estimators have been shown to have the potential to "clip the corner" of min[MSE($X\hat{\beta}$), MSE(Xb)] in figure 2. Some of these considerations are taken up below.

Optimal Pretest Critical Values

Using the MSE functions depicted in figure 2, the researcher is led to the possibility of choosing an optimal pretest critical value λ as a function of degrees of freedom and number of restrictions being considered. The risk function for the pretest estimator thus defined is a function only of λ, θ, m, and $T - k$. The noncentrality θ is an unknown nuisance parameter in the choice of optimal λ; intuitively, a reasonable choice of λ would be one that pulls MSE($X\beta^*$) close to the minimum of [MSE($X\hat{\beta}$), MSE(Xb)] over the range of θ. As discussed, the risk for the pretest estimator with $0 < \lambda < +\infty$ lies above the minimum of the risk functions for the restricted and unrestricted estimators for $X\beta$.

Depending upon a prior for θ, infinitely many ways exist for choosing an optimal λ. Most of the discussion here centers on a uniform or "blandly ignorant" prior for θ and reports the results of Brook (1976), Sawa and Hiromatsu, and Toyoda and Wallace. Such priors may be too conservative in the direction of large θ, since the very fact that the investigator is interested in a particular set of restrictions presupposes that he must have a prior belief that θ is small, although this is not always the case.[10] The main value in deriving optimal pretest critical values with a uniform prior is to reveal more about the nature of the risk functions. Such critical values also represent a "safe" position for the pretester who has a prior on θ heavily weighted towards zero—safe, that is, when his test statistic is larger than the "optimal" critical value.

error in the restrictions $Q'\beta = q$. Also, θ is bounded above by $(\partial_1/2\sigma^2)(H'\beta - h)'(H'\beta - h)$ and below by $(\partial_m/2\sigma^2)(H'\beta - h)'(H'\beta - h)$, where ∂_1 and ∂_m are, respectively, the largest and smallest characteristic roots of the matrix $(H'S^{-1}H)^{-1}$. For a given problem, H, h, S^{-1}, and hence ∂_1 and ∂_m are known; σ^2, though unknown, does not depend on the validity of the restrictions. Thus, θ is proportional to the sum of squares of restriction errors. A prior on θ that is, say, uniform is also a uniform prior on the sum of squared errors of a set of restrictions; all nonnegative values are equally likely.

[10] Dropping variables mechanically via a stepwise regression package is the obverse. The investigator must feel that the regressors are important; otherwise, why include them in the original regression? Similarly, dropping principal components of the regressors associated with small characteristic roots of the $X'X$ matrix and other ad hoc methods for dealing with ill-conditioned design matrices (multicollinearity) essentially impose restrictions whose associated θ may have no inherent prior weighting toward zero.

The two sets of "optimal" pretest critical values given in table 2 are from Brook (1976) and Toyoda and Wallace. The Brook criterion follows Sawa and Hiromatsu but extends to more than one restriction. The criterion is to find the pretest critical value λ^* that minimizes the maximum regret (maximum risk difference) between $\text{MSE}(X\beta^*)$, $0 < \lambda^* < +\infty$, and the minimum of $[\text{MSE}(X\hat{\beta}), \text{MSE}(Xb)]$. In other words, regret is defined as $\text{MSE}(X\beta^*) - \text{MSE}(X\hat{\beta})$ for $0 \leq \theta \leq m/2$, and $\text{MSE}(X\beta^*) - \text{MSE}(Xb)$ for $\theta \geq m/2$ (see figure 2).

Notes: For $m = 1, 2, 3$, and 4, $\bar{\lambda} = 0$, and $\alpha(\bar{\lambda}) = 1$ for all values of $T - k$, not just those listed. The notation n.c. means not calculated. The λ^* and $\alpha(\lambda^*)$ columns are from Brook (1972, table 5.1) and the $\bar{\lambda}$ and $\alpha(\bar{\lambda})$ columns are from Toyoda and Wallace (table 1).

By numerical integration, and for various degrees of freedom, Brook chooses λ^* values that equate the maximum regret on either side of $\theta = m/2$. Any values for λ other than the λ^*'s decreases the maximum regret on one side of $m/2$ at the expense of increasing maximum regret on the other side of $m/2$.

Toyoda and Wallace, assuming a uniform prior on θ, derive optimal values for the pretest critical values $\bar{\lambda}$ by integrating out θ; that is, $\bar{\lambda}$ is chosen by minimizing the difference between $\text{MSE}(X\beta^*)$ and the minimum of $\text{MSE}(X\hat{\beta})$ and $\text{MSE}(Xb)$ over θ. The area minimized is the shaded area in figure 2. The proof of convergence of the integral and other details are provided in Toyoda and Wallace.

Only a selected number of λ^*, $\bar{\lambda}$ critical values are given in table 2. The reader is referred to the Sawa and Hiromatsu, Brook (1976), and Toyoda and Wallace references for additional values. Table 2 also gives significance levels corresponding to the critical values under the central F null hypothesis.

The most striking feature of the critical values generated by minimax regret is their invariance across degrees of freedom. Of course, this invariance leads to considerable variation in pretest significance levels. In contrast, the minimum average risk values are much smaller for small degrees of freedom, being precisely zero for restriction sets of four or fewer, regardless of regression degrees of freedom. This result is because of the small potential for gain in minimizing the integral over θ unless m is fairly large. Thus, on the whole, the Toyoda and Wallace criterion is more favorable to ordinary least squares under a uniform prior. It is worth repeating that, with strong prior on θ weighted towards zero, the minimum average risk critical value could be arbitrarily increased. As numbers of restrictions and regression degrees of freedom get large, the two critical values λ^* and $\bar{\lambda}$ tend toward 2 as indicated by table 2.[11] This implies a symmetry of regret functions for $\lambda = 2$ for large degrees of freedom around $\theta = m/2$.

Brook (1976) produces some results of the relative efficiency of pretest estimators based on the minimax critical value λ^*. He defines

[11] There are no mathematical results in any of the papers cited to support this comment.

relative efficiency as the ratio of the risk of the restricted estimator to the risk of the "optimal" pretest estimator for $\theta \leq m/2$. For $\theta > m/2$, the numerator in the efficiency index is changed to risk of the unrestricted estimator. Graphs of efficiency for $m = 2$, $T = 60$, and $k = 4$, 6, and 8 indicate minimum efficiency at more than 75%. Maximal efficiency is for $\theta = 1$ and is greater than 90% for all three cases considered. Brook (1972) went on to consider maximizing the minimum relative efficiency over θ with respect to λ. This results in slightly larger critical values for $m = 2$ than those obtained by minimax regret (see Brook's table 5.5). Brook's results on minimum efficiency are sketchy but tend to confirm that the worst outcome using his critical values are not too bad. If one concentrates on the β vector rather than $X\beta$ in defining risk, the potential for gain (and loss) in pretesting becomes magnified depending upon how ill-conditioned is the design matrix. Hence, the apparent control of relative risk of the minimax critical value is altered with the choice of risk function.

Stein-Type Estimators

A leading contender to conventional pretest estimators is an estimator that originated in a paper by Stein. His basic notion is to give up unbiased estimators in multivariate situations in favor of reduced MSE. As an example of what is involved, consider $\bar{X}$ as an estimator for μ, given a random sample of size n from any distribution whose mean μ and variance σ^2 exist. As is well known, the sample mean $\bar{X}$ is unbiased for μ, with variance σ^2/n. Is there some other estimator $\hat{\mu}$ with MSE less than $\bar{X}$? The answer is yes, if one is willing to take some bias along with it. Let

$$\hat{\mu} = a\bar{X}, \tag{24}$$

where a is a constant, the mean of $\hat{\mu}$ is $a\mu$, and its variance is $a^2\sigma^2/n$. The MSE is

$$E(\hat{\mu} - \mu)^2 = (a - 1)^2\mu^2 + a^2\sigma^2/n, \tag{25}$$

and choosing a to minimize the MSE gives

$$a^* = \frac{\mu^2}{\mu^2 + \sigma^2/n}, \tag{26}$$

where a^* is smaller than unity, which is typical for Stein-type estimators. The unbiased estimator $\bar{X}$ is "shrunk" by a^*, producing a bias towards zero, but the variance of $a^*\bar{X}$ is smaller than the variance of $\bar{X}$, so that judicious choice of the "shrinker" results in a reduction in MSE.

As is often the case in constructing such estimators, a^* is a function of unknown parameters, including the one of interest. One could estimate a^* by $\bar{X}$ and s^2, the sample variance, but the sampling properties of the resulting estimator are no longer so easily understood. Such questions have been investigated by Holland.

Efron and Morris summarize the difficulties involved with Stein-type estimators, difficulties that they strongly take issue with.[12] They mention distrust of MSE criteria, lack of familiarity with the techniques, as well as the lack of a universal rule of application, requiring various adaptations to various estimation situations, and some feeling among statisticians that one does not buy much with the complications. Efron and Morris give three applications, making their own adaptation of Stein-type estimators, and they claim increased efficiency (relative mean square) over maximum likelihood estimators by several orders of magnitude.

They also state that "The most favorable situation for these estimators occurs when the statistician wants to estimate the parameters of a linear model that are known to lie in a high dimensional parameter space H_1, but he suspects that they may lie close to a specified lower dimensional parameter space $H_0 \subset H_1$. Then estimates unbiased for every parameter vector in H_1 may have large variance, while estimates restricted to H_0 have smaller variance but possibly large bias. The statistician need not choose between these extremes but can instead view them as endpoints on a continuum and use the data to determine the compromise between bias and variance through an appropriate empirical Bayes rule, perhaps Stein's or one of the generalizations of this report" (pp. 46–47, footnote omitted).

In a recent, as yet unpublished paper, Aigner and Judge give a general discussion of Stein-type estimators in precisely the situation described in the Efron and Morris quote. They discuss two types of risk functions on the regression parameter space and give conditions under which Stein-type estimators dominate the pretest estimator for both risk functions. Further, they apply a particular Stein-type estimator to three empirical situations and make evaluation of the results.

[12] The bibliography on Stein-type estimators in the Efron and Morris publication is extensive.

Referring to the general linear model of full rank with a set of potential restrictions on the parameter space, the Aigner and Judge paper uses the following version of a Stein-type estimator. Define $c = (m - 2)(T - k)/(T - k + 2)m$, and take m (hence k) ≥ 3.[13] Let $\beta = \hat{\beta}$ if $u \leq c$ and $= (1 - c/u)b$ if $u > c$, where u is the usual calculated F-statistic based on restricted and unrestricted error sum of squares, $\hat{\beta}$ is the RLS estimator, and b is the unrestricted OLS estimator. This is only one version of the Stein-type estimators considered in the Aigner and Judge paper, but it is the one they used in application. It combines the characteristics of a pretest estimator with a "shrinker." If u is large, $\tilde{\beta}$ approaches the OLS estimator, and if $u < c$, the restricted estimator is chosen. Otherwise, the estimator $\tilde{\beta}$ is a positive fraction times the OLS estimator.

For $m \geq 3$, $\tilde{\beta}$ can be shown superior to both b and any conventional pretest estimator using the MSE function $\text{MSE}(\beta^{est} - \beta)'X'X(\beta^{est} - \beta)$, where β^{est} is any of the estimators. How much better is the question. Unlike the Efron and Morris applications, the Aigner and Judge results are not persuasive that "one buys much with the complications." Aigner and Judge also show that altering the risk function to $E(\beta^{est} - \beta)'(\beta^{est} - \beta)$ produces more stringent requirements for theoretical dominance of Stein-type estimators, conditions that are not met in two of their three applications.

Concluding Remarks

The focus of this paper is on properties of pretest estimators in linear regression, where a single test of a set of linear restrictions on the β space leads sequentially to a choice of OLS or RLS estimators. Pretest estimation of variances or other parameters are related, as is stepwise regression programs that sequentially delete (or add) variables in several steps. The paper relies heavily on Bancroft, Toro-Vizcarrondo, and Brook (1972) as cited previously. Others who have contributed to the literature on pretesting include Bock, Judge, and Yancey (1973a, b), Han and Bancroft, Judge, Yancey, and Bock, and Huntsberger. The most complete bibliography available on the analysis of all such practices is in an unpublished paper by Bancroft and Han.

In a broader sense, pretest estimators fall within the class of all estimators that consciously make a trade for smaller variance at the risk of bias. A Stein-type estimator was selected for brief discussion in this paper. However, the Hoerl and Kennard ridge estimator also could be included in the discussion, as well as such practices as reducing instrumental variables in single or simultaneous equation models by the use of principal components. For a reference on the latter, see Massey.

Viewing exact restrictions as prior information and pretesting as evidence that the investigator is uncertain about those restrictions, other candidates are brought to mind as alternatives to pretesting, namely, procedures that involve a more careful statement of the degree of ignorance of the investigator at an early stage. Nonstochastic inequalities rather than exact restrictions are a case in point. Similarly, uncertainty about restrictions can be couched in a stochastic statement, adding random errors to relationships that are suspected to hold. Stochastic priors may be used in either a classical or Bayesian framework, and the reader may be introduced to these subjects in a linear regression model in Zellner and in Theil and Goldberger, the Zellner book providing analysis of the Bayesian approach.

Stochastic restrictions provide a richer framework for revealing the investigators priors. However, Theil derived a "compatibility test" for stochastic priors in a classical framework that conceivably might reveal to the investigator that, if his basic model is right, there is a large chance that his priors are wrong, or vice versa. If subsequent action is taken in estimation based on the compatibility test, one is right back to the focus of this paper.[14] Likewise, a Bayesian might be led to modify his priors on the basis of a data confrontation. Bad priors can lead to badly biased results in Bayesian as well as classical approaches.

The points covered in the main body of the paper that should be of interest to the applied researcher are as follows. (*a*) Imposing restrictions in regression reduces variances, but false

[13] A requirement for the Stein-type estimator to dominate the pretest estimator in quadratic risk is for the number of restrictions to be at least three in number.

[14] The compatibility test is simply an F-test for pooling data from different sources in a generalized (Aitken-type) regression model when degrees of freedom are too small in one data set (the priors) to run separate regressions. For discussion of the pooling test in this case, see Fisher.

restrictions introduce bias. If data are cheaply available, modeling errors in the direction of overspecification of numbers of variables (or otherwise not accounting for prior information) can be offset, since in most contexts variances reduce as degrees of freedom increase. Mistakes in the other direction—imposing false restrictions—cannot be overcome by increasing the sample size. Biasedness persists with large samples.

(*b*) Probability distributions of pretest estimators, where the final model is selected on the basis of a test outcome, are complex. Standard errors and other measures of reliability as reported in a final least squares run are misleading, sometimes badly so. Hence, the conventional practice of reporting regression coefficients as significant at, say, the 5% level is usually misleading.

Whether to pretest only can be decided using a risk (or utility) function that weighs potential gain from reduced variance against risk of bias. Such a risk function may be implicit or explicit. One such function, arbitrary but exhibiting proper attitudes toward badness of bias and goodness of smaller variance, is quadratic risk or MSE.

Using a particular MSE, one can derive and graphically demonstrate the trade-offs involved as they vary with the truth of the relevant restrictions; that is, the noncentrality parameter in the test statistic may range from zero for valid restrictions to an arbitrarily large number for sufficiently invalid restrictions. (The noncentrality parameter is usually associated with power of the test.)

For the particular quadratic risk function graphed in figure 2, the pretest estimator is always worse than the best of the OLS and RLS estimators over all values of the noncentrality parameter. If the value of the noncentrality parameter in a particular problem is known, the choice is simple. Pretesting arises because the researcher does not know that value.

The risk function for the pretest estimator depends on degrees of freedom, number of restrictions tested, the noncentrality parameter, and the critical value (probability of type one error) for the pretest. For the extreme values of zero and infinity for the critical value for the test, the pretest estimator becomes identical to, respectively, the OLS and RLS estimators. For any nonzero, finite pretest critical value, the risk of the pretest estimator is less than risk for OLS over a range of the noncentrality parameter ($0 \leq \theta \leq m/4$), reaches a maximum somewhere to the right of its intersection with risk of the RLS estimator, and becomes asymptotic to risk for the OLS estimator for arbitrarily large values of the noncentrality. The minimum of the risks for the "never restrict" and "always restrict" estimator provides a lower bound for the risk of pretesting.

(*c*) Optimal pretest critical values have been derived by finding those values that pull the risk of the pretest estimator close to its lower bound. One method is to minimize the maximum deviation of the pretest risk from its lower bound over the noncentrality. This results in critical values of about 2.0 in F testing (about $\sqrt{2}$ in t-tests), which are very stable independently of degrees of freedom. Another method is to minimize the area between the risk of the pretest estimator and its lower bound over the noncentrality. Since this latter method gives equal weight to very large noncentralities, it results in a verdict for never restricting unless one is dealing with at least five restrictions. Thus, given the risk function used and the criterion of minimizing areas, t-testing to delete variables is, for example, ruled out. Of course, one could weight the area to be minimized, given prior information on θ, and this would yield a different result.

From the current results one might try to formulate some rules. The following are suggested but are surely not hard and fast. (*a*) If the researcher thinks certain restrictions are valid based on theoretical consideration or experience in similar situations, impose them without testing. This is a rather innocuous comment, since research must begin by at least some arbitrariness.

(*b*) Using stepwise regression programs to delete variables mechanically is dangerous. If the researcher believes that a variable is important enough to have gathered data for it, his prior on the noncentrality for deleting it is probably not bland. On the contrary, the prior for testing that a coefficient is zero on a variable already included should weight toward large values of the noncentrality, and the Toyoda and Wallace optimal critical values dictate against t-test deletion of variables even with a bland prior.

(*c*) In data-pooling tests, one is never sure whether the structure varies across the sets, but in many cases where structures seem to change slowly, such as cross-section relationships over time, the Toyoda-Wallace critical values are probably overly conservative, leading to not pooling when in fact one should

pool. Here, the Brook critical values may be appropriate, and if the investigator gets an F-statistic smaller than the Toyoda-Wallace critical values, pooling is indicated.

(*d*) Beware of standard errors, t-tests, etc., as reported in a final regression after pretesting. They are misleading and are surely biased in the direction of indicating significance when in fact there may not be any.

In summarizing the material for the practical researcher, it is difficult to avoid a pious Golden Rule: "go thou and construct true models." Such advice is, of course, empty. However, in my opinion, statistical procedures substitute rather poorly for rigorous modeling based on the foundations of the field of application. Rather, statistical technique is a complement, not a substitute. Nevertheless, anyone with experience in empirical work knows that learning is a sequential process and that theory sometimes falls short of providing the sort of prior information one would like. Occasional sinning, therefore, may be inevitable but not necessarily fatal.

Effects of Energy Cost Increases and Regional Allocation Policies on Agricultural Production

Richard M. Adams, Gordon A. King, and Warren E. Johnston

Some of the impacts of energy cost increases and reduced supplies on the product mix of annual field crops and vegetables in California are analyzed. A quadratic programming model including risk is used to evaluate the effects of increased energy costs and reductions in fertilizer and in fuel supplies. The model includes a demand matrix of some nine field crops and twenty-eight seasonal vegetables. The study also considers the relative impact of energy changes on producer and consumer welfare. Results suggest continued viability of vegetable production but differential consumer and producer impacts associated with energy changes.

Key words: California annual crops, energy costs, quadratic programming, risk.

The 1973 Organization of Petroleum Exporting Countries (OPEC) oil embargo brought into sharp focus the impact on agriculture of cost increases associated with energy (gasoline and diesel fuel) and energy-based inputs (nitrogen fertilizers and pesticides). State and intrastate allocation schemes were proposed. Although present supplies are not restricted, the future may see a repeat of the 1973 occurrence. An unstable energy input structure, resulting from a combination of institutional and market forces, is apt to have a significant influence on both producers and consumers. Producers are affected by changes in relative costs and prices and consumers by changes in product prices. Such energy cost increases have a differential effect on various crops depending, in part, on the importance of such inputs in production costs. The basic thrust of this paper is to quantify the impact of such energy cost increases and quantitative restrictions on the product mix of annual field crops and vegetables in California. The study also raises some methodological points of more general applicability.

Three energy-related inputs that substantially affect the agricultural productivity of land and labor are nitrogenous fertilizers, pesticides, and fuel inputs. The 1972 estimated costs (preembargo) of energy inputs for field crops studied ranged from $12 to $46 per acre, whereas costs for vegetables ranged from $43 to $256 per acre (see table 1). Any analysis of an increase in energy costs requires considerably more information. On the production side, data are required on total variable costs and the associated yield response functions to these inputs. Information on resource availability such as land and water are required. Further, information must be obtained as to the probable price response associated with energy cost increases and with changes in relative prices resulting from a changed product mix. On strictly qualitative grounds, it is difficult to argue the direction of change in production for these field crops and vegetables. Although vegetables have higher costs of energy-related inputs, these costs expressed in relation to total variable costs show as much variation within as between groups (see table 1).

In view of this apparent inability to discern qualitatively any probable impacts, the specific objectives of this study are to evaluate the price, quantity, acreage, and "welfare" effects of (*a*) changes in statewide and subre-

[a] Includes both diesel and gasoline fuel used directly in production of crops.
[b] Cost reflects prevailing market price (1972) for pesticides (petroleum based) and nitrogenous fertilizer (natural gas based) inputs. Thus, the per acre energy cost for each input represents total cost of material input, including the energy component (petroleum and natural gas) and nonenergy components.

gional energy restraints, (*b*) increases in energy costs, and (*c*) changes in product demand levels. The study also provides some insight as to the effect of introduction of a yield variability coefficient, representing relative risk, in a normative model.[1] Further, the study indicates the applicability of a quadratic programming solution with price-quantity functions included directly into the objective function rather than segmented demand functions reported previously in this *Journal* (Duloy and Norton, Hazell and Scandizzo).

In terms of presentation, the analytical framework is developed with reference to previous research. The results for a base period model (1969–72), including the effect of a risk factor and the effect of statewide versus regional energy restraints, are presented first. Projected 1977 outcomes are quantified, where energy costs and demand levels are varied. The effects of further restrictions on nitrogen and fuel supplies are explored, and in the final section some rough measures of welfare gains and losses to producers and consumers are indicated.

Analytical Framework

Mathematical Model

The basic quadratic programming model is a modified version of the one shown by Takayama and Judge and discussed recently by Duloy and Norton. Specifically, the objective function is of the form:[2]

$$(1)\quad \max \Pi = q'(a + 0.5\,Bq) - c'q^* - c'Dq^*,$$

where q is a vector of aggregate activity levels and q^* is a vector of regional activity levels, expressed in quantity units (e.g., 1,000 hundredweight or 1,000 tons); a and B are elements of the linear demand structure of the

[1] The "variability coefficient" as discussed by Carter and Dean differs slightly from the more widely used "coefficient of variation." Specifically, the variance is defined as the variance of the "random" portion of a time series (reflecting the influence of noneconomic factors such as weather) as computed by the variate difference method, while the mean represents the mean of the last five years. For a detailed discussion, the interested reader is referred to Tintner.

[2] This specification differs slightly from that presented in this *Journal* by Hazell and Scandizzo and Simmons and Pomerada. While these authors express activity levels in hectares and then convert to quantity units consistent with the demand functions through inclusion of average yield matrices, this study presents activity levels directly in terms of demand units and subsequently converts to acreage units. Additionally, the term containing the risk element ($c'Dq^*$) does not appear in the Duloy and Norton formulation and differs from that used in Hazell and Scandizzo and Simmons and Pomerada.

form $P = a + Bq$, where P is an $n \times 1$ vector of prices, a is an $n \times 1$ vector of constants, and B is a negative diagonal matrix of price-quantity slope coefficients (implying zero cross-effects at the farm level); c is a vector of variable cost per unit of output for particular crops by region and soil type; and D is a diagonal matrix of yield variability coefficients.[3]

The objective function is bounded by a convex constraint set of the form $Aq \leq b$, where A is an $m \times n$ matrix of input-output technical coefficients, and b is an $m \times 1$ vector of regional resource availability levels. The maximization of the objective function subject to the restraints is analogous to maximization of the sum of producers' and consumers' surplus under the competitive framework if one is dealing strictly with final products. A further discussion of this issue is in a final section, since there are some intermediate commodities such as feed grains in this model.

On a methodological note, the A matrix consists of 370 production activities and the demand matrix B includes slope coefficients for nine field crops and for twenty-eight seasonal vegetables. The solution procedure incorporates the slope coefficients and intercepts directly into the objective function rather than the segmented demand procedure suggested by Duloy and Norton.[4]

Treatment of Risk

Incorporation of risk in quadratic models was discussed twenty years ago by Freund. Lin, Dean, and Moore have shown the validity of the risk-averse behavioral assumption for crops with large variation in income. Recently, Hazell and Scandizzo have renewed interest in the inclusion of risk in large programming models. Essentially, they add a risk aversion coefficient and a variance-covariance matrix of gross activity returns such that price and marginal returns are equated for each activity. Simmons and Pomerada's study of Mexican vegetable exports utilizes this procedure in testing alternative values of the risk aversion coefficient (from 0 to 1.5) to compare actual with model results.

In this study, risk is confined to yields. Input costs and price-forecasting equations are assumed to remain nonstochastic. The yield coefficient of variation, estimated by the variate difference method (Carter and Dean), is used to modify regional variable cost per unit of output to give a risk cost for each crop. Simmons and Pomerada, after performance of sensitivity analysis, used a constant risk aversion coefficient across crops.[5]

Demand Relationships

Emphasis is on the effect of changes in California production on price. Thus, the general specification of the price-forecasting equations was of the form: season average price received by farmers in California for commodity i is a function of California production, other U.S. production, existing U.S. stocks where applicable, and U.S. aggregate disposable personal income. This formulation was used for all seasonal demand relationships and crops with the exception of cotton, processing tomatoes, sugar beets, and safflower, where market conditions were such that the model seemed inappropriate due to suspected simultaneity. Estimates of these demand relationships were developed from outside sources.[6] The econometric analysis for vegetables indicates significant seasonal variation, using the Logan and Boles testing procedure, with the exception of two crops. Table 2 contains price-quantity relationships as well as R^2's for selected vegetable and field crop price-forecasting equations. The statistical significance of demand coefficients for some

[3] An alternative treatment of risk using yield variability coefficients is to modify the last term, i.e., replace $c'Dq^*$ with $q^{*\prime}CDq^*$, where C is a diagonal variable cost matrix of elements corresponding to the elements of the c vector. Thus, the risk marginal cost rises with the square of quantity produced, and hence the greater the production of a specific commodity, the greater the risk. Such a development would be consistent with conventional risk-diversification procedures. This treatment was not attempted due to expected computational difficulties associated with reformulation of the existing mathematical model objective function.

[4] The quadratic programming problem was solved using a nonlinear programming algorithm developed at the University of California, Berkeley, by Best. This algorithm, identified as FCD (Feasible Conjugate Direction), provided a powerful mechanism for solving problems with nonlinear objective functions constrained by a system of linear equations when interfaced with the University of California, Berkeley, ALPHAC simplex algorithm. The integration of this system of software with the speed of the CDC 7600 provided an expeditious means for solving the numerous parameter alternatives to which the large study problem was addressed. Individual execute times for all model solutions were less than 42 seconds per run.

[5] The yield variability coefficient was used to derive an additional or "marginal" risk cost for each crop by multiplying the variability coefficient times the respective crop per acre variable cost. Then, crop variable costs were adjusted by the addition of this "marginal" risk cost, changing the relative cost structure among crops.

[6] By crop, these estimates are: cotton (Blakely), processing tomatoes (King, Jesse, and French), sugar beets (Bates and Schmitz), and safflower (Houck).

Source: Adams.

[a] Independent variables, other than California production, were evaluated at mean levels and added to the intercept term, resulting in a general price-forecasting equation of the form: $Pc_t = a_t + d_tQc_t$. Units of the intercept terms are in dollars per hundredweight for all vegetables (excluding processing tomatoes), dry beans and rice, and in dollars per ton for processing tomatoes and sugar beets. Exceptions are feed grains (dollars per bushel) and cotton (cents per pound).

[b] Units of the slope coefficients are 1,000 hundredweight for most vegetables, rice and dry beans, and 1,000 tons for sugar beets. Exceptions include cotton (1,000 bales) and processing tomatoes (tons).

[c] Due to statistical insignificance of the estimated slope coefficient, the slope coefficient is derived from other season price-flexibilities for the same crop, at relevant price and quantity levels.

[d] Slope coefficient derived from secondary sources (see footnote 6).

[e] The estimated feed grain intercept and slope coefficient are used interchangeably for barley, corn, grain sorghum, and wheat within the base and projection models.

crops is disappointing, forcing the use of slope coefficients for other seasons (table 2).

Production Coefficients and Restraints

The development of the data set for this analysis follows the procedure employed by Shumway et al. More specifically, the data requirements for the model include (*a*) specification of the production regions and the associated cropping activities; (*b*) the regional constraints on land, water, energy, and processing capacities; (*c*) yields and costs for regional cropping activities; and (*d*) the input-output, or technical coefficients for each cropping activity.

Regional definition is facilitated by classification of three key regional determinants—climates, soils, and water costs. To achieve a sufficient level of homogeneity in these factors, fourteen production regions were delineated, each with two irrigable soil types.

Two types of constraints are included in the study: physical resource constraints (land, water, and energy inputs) and institutional constraints (maximum state processing capacity). The constraint levels apply to both the base period and the projection year. Resource availability constraints are adjusted to account for excluded crop requirements, based on actual and projected acreages of perennial crops.

Data on yields and variable costs are obtained from secondary sources (University of California, Agricultural Extension Service) and from consultation with extension personnel and industry representatives. Variable costs of production are disaggregated into energy and nonenergy components to facilitate the measurement of impacts resulting from varying energy cost assumptions. Projected yields are derived from secondary sources. Variable costs for the projection year (before modification to reflect energy cost assumptions) are based on actual and projected movements in nonenergy agricultural input prices.

Base Period Model

The 1969–72 base period model is needed for the comparative static analysis of the projections models. Equally important is its use in analyzing two important questions: (*a*) what effect does the inclusion of a risk factor (yield variability) have on the resulting acreage, production, and prices of model versus actual outcomes? and (*b*) what are the effects of statewide versus regional energy restraints on these same variables?

Effect of Inclusion of Risk Factor

The results of this study provide additional evidence on the importance of specifying risk in normative programming models. Admittedly, our treatment of risk, measured by a yield variability coefficient, is but a first approximation to the more comprehensive analysis proposed by Hazell and Scandizzo and the sensitivity analysis done by Simmons and Pomerada.

The yield variability coefficients for various field crops and vegetables indicate greater variability for vegetables than for field crops (table 3). The effect of introduction of this "risk" factor into the analysis was that acreages of thirteen of the sixteen crops and production of twelve of the sixteen crops were closer to 1969–72 actual levels than when no risk factor was included. Prices (for the weighted average

Source: Adams; for variability coefficients, Carter, Jensen, and Dean.
Note: 1969–72 base model is the statewide energy restraint model.
[a] The ranges in yield and gross income for vegetables are for various seasons.
[b] Data are shown for annual production for the nine fresh vegetables, aggregating the 27 separate seasonal levels used in the analysis.

of seasonal items) were closer to 1969–72 prices for eleven of these sixteen crops. The results are as expected—vegetable acreage (higher yield variability) decreased in the aggregate, while field crop acreage increased.

Review of possible limitations of this approach may lead to better modeling in the future. First, the amount of "improvement" was marginal for some crops. The acreages of safflower, onions, and processing tomatoes are particularly high in relation to actual values. For the latter two crops, acreage is largely contracted by processors; thus, the models do not reflect actual market conditions. For safflower, another contracted crop, the fault appears also to be partly related to the demand specification, since both price and quantity are above 1969–72 levels. Higher production levels for onions and tomatoes interact with the price-forecasting equation to give lower prices. Thus, the observed deviations from actual values (for both nonrisk and risk model specifications) may be partially attributable to demand parameters.

A second problem lies in the use of one yield variability coefficient per crop for the state. A more accurate specification would have yield coefficients vary by region within the state as quantified earlier by Carter and Dean. However, consideration of computational aspects as well as divergences for regional definition between studies precludes the use of regional coefficients. A third question relates to the use of yield versus gross income variability coefficients. No evidence is offered on this point, but a comparison of yield and income variation coefficients in table 3 suggests that such a specification might lower vegetable production in relation to field crops. If income variations are used, questions relating to net versus gross income are important. Further, the work by Just and others suggests the importance of government programs on risk and supply response.

In summary, these findings are offered as indicative of directions for research rather than a convincing argument as to how well normative models can predict—an unlikely goal.

Effect of Statewide versus Regional Energy Restraints

In this section, a comparison is given between two models reflecting actual conditions during the oil crisis. In the first model, energy inputs are treated as perfectly mobile within and across production regions (i.e., only a statewide constraint, set at actual 1969–72 consumption levels, is operative for each energy input). This formulation is consistent with the readily available energy supply situation of the late 1960s and early 1970s. However, as energy input supplies adjusted during the events of 1973–74, several allocation programs were advanced, including a mandatory regional allocation policy. An implicit rationing scheme, in turn, was imposed on agricultural users based on past purchases from respective suppliers. While not totally fixing input supplies within a specific region, this scheme did reduce input mobility. To examine the impacts of a rigid regional allocation policy, a second base model for 1969–72 was evaluated, with each region receiving levels of energy inputs comparable with actual recorded usage.

A comparison of these base model results with actual acreages and seasonal and annual price levels is provided in table 4. The results with respect to acreage levels and prices are not totally unexpected. Imposition of regional energy constraints generally reduced crop acreages, particularly in certain field crops, resulting in an attendant rise in commodity price levels.[7] All commodities but rice experience acreage reductions, reflected in the higher equilibrium prices. Vegetable acreages appear less sensitive to such an allocation scheme, with the exception of processing tomato acreage, which declined sharply (approximately 40%) under the regional energy allocation model.

On a regional level, production patterns displayed no major adjustments across models. While the major production regions experienced reductions in crop acreages, such reductions were similar across regions and largely consistent with the aggregate results. For example, the production pattern of the central coast of California remained primarily oriented towards fresh vegetables; emphasis on specific field crops (e.g., cotton and feed grains) in the Central Valley continued. However, Central Valley production did display rather sharp reductions in cotton and processing tomato acreage with the imposition of regional restraints.

Production and prices varied considerably.

[7] The rise in feed grain prices would take place only without increased levels of interregional shipments. It seems reasonable that other regions would experience similar energy cost increases.

Table 4. Effect of Introduction of Regional versus Statewide Energy Restraints on Acreage, Production, and Prices with Base Period Comparisons

Crop	Acreage			Production			Prices		
	Actual	Energy Restraints		Actual	Energy Restraints			Energy Restraints	
	1969–72	Statewide	Regional	1969–72	Statewide[a]	Regional	Actual	Statewide	Regional

Source: Adams.
Note: Models include risk factor.
[a] The relationship between production levels and acreage reflects the "optimal" location patterns arrived at in the model solutions. In other words, yields per acre under model production exceed those actually obtained, as reflected in aggregate county data.

The value of production of field crops in the statewide energy restraint model was 96% of actual and in the regional energy restraint model 99% of actual. For vegetables, comparable levels were 125% and 114%, respectively. Total value of production under the statewide restraint was 112% of the 1972 level. Under the regional restraint model, total value of production was 107% of actual level.

Projected 1977 Model Outcomes

This analysis, undertaken during 1974 and 1975, focuses on two major problems: (*a*) what might be the effect on acreage and production under alternative energy cost? and (*b*) what might be the effects on acreage and production of further reductions in nitrogen fertilizer and fuel supplies? The basis of comparison for projected 1977 outcomes is the 1969–72 model with regionally constrained energy levels.

Effects of Changes in Energy Costs and Demand Levels

Several alternative levels of energy costs and product demand levels were explored, but only two alternative energy cost levels are presented here. The two energy input cost structures are referred to as medium-cost (Mc) and high-cost (Hc) models. The first portrays a cost increase equal to the observed or anticipated rise in all farm nonenergy inputs for the period 1972–77 based on data from *Agricultural Prices* (USDA). This medium-cost model results in cost increases for energy and nonenergy costs of 50% above the 1972 level. The high-energy-cost model (Hc) increases energy costs by 70% above 1972 levels, while nonenergy costs are held at the 50% increase.

Three alternative demand assumptions are included in the analysis. The results of the medium-demand assumption, featuring an upward adjustment of the price-forecasting equation intercept by 50%, are reported here.

The medium-demand, high-cost model approximates most closely the current situation and serves as a base model in the following discussion.

The effect of an increase in energy costs, under a given level of product demand (as reflected in price-forecasting equation intercept adjustments from 1972 levels for all crops), is to increase acreage and production of field crops and decrease acreage and production of vegetables (table 5). The overall acreage level increases by about 1%. These results are consistent with expectations, given the high energy requirements of vegetables. It cannot be argued that this is an equilibrium solution unless the full consumer demand reactions are included. This is particularly difficult for crops that are intermediate products (e.g., feed grains) or that have multiple outlets (e.g., vegetables).

Effects of Reduction in Input Quantities

The reduction in input levels would be expected to reduce production, but would this decrease be greater for vegetables or field crops? Results in table 6 indicate that vegetable production is maintained to a greater extent than is field crop production. Acreage of field crops shows a marked increase to reductions in fertilizer supplies. This observation is consistent with lower yields associated with nitrogen reductions and the specification of activity levels, in terms of quantity units, rather than acreage. Thus, given surplus irrigable land in most regions, the solutions reflect the substitution of land for fertilizer.

Combined effects of nitrogen fertilizer and fuel reduction dampen acreage levels from both nitrogen reduction models and 1977 energy level results. Vegetable acreages in all but the low-demand models increase when compared with the 1972 regional energy model. Within the vegetable commodity group, reductions in broccoli, cauliflower, cantaloupe, and potato acreages are offset by substantial expansions of tomato, lettuce, and onion acreages. Such a response appears to indicate that California will remain a significant supplier of vegetables even under rather adverse energy input conditions.

Table 5. Effect of Changes in Energy Costs on 1977 Model Acreage and Production under Medium Demand

	Acreage		Value of Production	
	With Energy Cost		With Energy Cost	
Crop	50% of Above 1972	70% of Above 1972	50% of Above 1972	70% of Above 1972
	-- 1,000 Acres ---		- Index Number[a] -	
Field crops	1,290.9	1,459.9	85	100
Vegetables	942.4	794.0	119	100
Total	2,233.3	2,253.9	108	100

Welfare Gains and Losses

Theoretical Arguments

The maximand of the mathematical model is the sum of the areas under the crop demand curves (at farm level) minus supply costs (including risk) associated with the optimal quantities of each crop activity. If one was in a world of markets for final products without time, form, and space dimensions, it would be possible to discuss producers' and consumers' surpluses under the usual caveats associated with such concepts. In this study it is useful to use these concepts, but only under strong assumptions. For example, one might argue that the products are such that the income compensated demand curves are approximately equal to the ordinary demand curves (Dean and Collins). Since many commodities are being considered, it is more tenable to argue that the measures of producers' and consumers' surpluses are the upper bounds to such values.

Market dimensions are ignored, since prices are considered equal at all points in the state. Raw product prices are assumed equal regardless of form (fresh or processed), except for separate specification of fresh and processed tomatoes. The treatment of consumers' surplus must consider final products (e.g., fresh tomatoes) and intermediate products (e.g., feed grains). The measure of consumers' surplus measured at the farm level for a final product equals that measured at the retail level if one has demand functions at both levels separated by a constant dollar marketing mar-

Table 6. Effect of Reduction in Nitrogen Fertilizer and Nitrogen Plus Fuel on 1977 Acreage and Production

Item	Acreage			Value of Production		
	Field Crops	Vegetables	Total	Field Crops	Vegetables	Total
	1,000 Acres			Index Number[a]		
1977 base model	1,459.9	794.0	2,253.9	100	100	100
Reduced nitrogen (N)						
20%	2,062.1	806.2	2,868.3	90	98	96
40%	1,890.2	846.9	2,737.1	89	94	92
Reduced N and fuel

gin (R. King); that is, the two functions are parallel and the point of intersection of relevant demand and supply curves for different market levels is at the same quantity (raw product equivalent) level.

Discussion of consumers' surplus for intermediate products would be incorrect for a complete general equilibrium model, since consumers do not eat feed grains but rather meat and livestock products. Since livestock products are not included, the consumers' surplus associated with some of the field crops is a proxy for the resultant change in consumers' surplus in the final product market. Major emphasis in the analysis is given to change in consumers' surplus from one situation to another, rather than on the absolute magnitude of the values.

As to producers' surplus, this is a return above variable plus risk costs of production and is allocable to "land" (soil quality, water availability, and other restraints) and management. No distinction is made between resource owners and producers.

Empirical Findings

The effects on consumers' and producers' surpluses are discussed under four conditions; they are: (*a*) the effect of statewide versus regionally mandated energy allotments, (*b*) the effect of increased energy costs, (*c*) the effect of reduction in nitrogen supply, and (*d*) the effect of reduction of both nitrogen and fuel supplies.

The imposition of a regional energy allotment is compared with a statewide energy restraint for the 1969–72 base model. As shown in table 7, analysis 1, the regional restraint reduces the total value of the objective function by $264 million, with roughly equal absolute decreases in consumers' and producers' surpluses.[8] Consumer prices generally are higher and quantities consumed lower with the regionally constrained model (see table 3), thus reducing consumers' surplus by 36%. Producer surplus also is reduced by 19%, due to reductions in aggregate production and some changes in specific production patterns, such as a sharp reduction in cotton and processing tomato production in the Central Valley.

The effect of increased energy costs is examined using the 1977 models, which impose the regional energy restraints in all cases (see table 7, analysis 2). As energy costs are increased from 50% to 70%, the value of the objective function decreases by 21%, whereas energy costs are increased by about 13% above the medium base. The decrease in producers' surplus exceeds that for consumers' surplus (including the intermediate products in field crops), whereas the relative decrease is 19% for producers and 24% for consumers.

The effect of absolute reductions in fertilizer supplies are given in analysis 3 in table 7. Reductions of 20% and 40% show little change in

[8] The disaggregation of the objective function into its respective components was facilitated via calculation, across all crops, of net returns, where crop net returns are defined as the difference between gross revenue (determined at the "equilibrium" price levels as established in the solution procedure) and variable costs. This aggregate net return (to producers) was then subtracted from the total value of the objective function, with the resulting residual corresponding to the sum of the area above market or "equilibrium" price and below the price-forecasting equations (consumers' surplus).

[a] Results shown relate to moderate demand increase assumption with regional energy restraint.
[b] Base model is moderate-demand, high-cost increase shown directly above.

consumers' surplus when compared with the base model. Producers' surplus reductions of $48 and $213 million, respectively, are consistent with the expected optimal set of crop activities. The optimal quantities of each crop remain similar to the levels of the base model, but acreages expand to adjust for lower yields. Thus, producers' gross revenues do not change significantly, while production costs rise in proportion to the expanded acreage, resulting in lower net revenues. Since quantities are about the same, the demand functions give prices that are stable and thus consumers' surplus remains about the same.

The impact of reduced fuel supplies tends to fall on consumers rather than producers. Compare results of analysis 3, where nitrogen only is reduced, with analysis 4, where both nitrogen and fuel are reduced. For a given reduction (20% or 40%), producers' surplus remains fairly stable, whereas consumers' surplus drops sharply (for the 40% reduction, from $345.6 to $264.8 million). This result is due to a change in product mix, where the comparative advantage of commodities (field crops) with the less steeply sloped price-quantity relationships is enhanced relative to vegetable crops having steeper sloped price-quantity relationships. Therefore, the greater percentage reduction in vegetable commodities relative to field crops results in a more severe reduction in consumers' surplus vis-à-vis that of producers.

Viewed from a policy standpoint, information of the above type is needed for analyzing several issues pertaining to agriculture. For example, an important policy observation concerns the impact of combined energy reductions and high fuel costs. The relatively more severe impact on consumers associated with these adjustments suggests that subsidization of fuel in some cases may actually be of greater benefit to consumers than to producers. A similar comparison of the effects of high and low energy costs on consumers indicates that such transfer payments may result in a substantial benefit to consumers.

An additional policy area, though admittedly one not directly addressed in the study, concerns nitrate pollution associated with agricultural activities. Based on model results, it appears that the cost of a policy aimed at reducing ground and surface water nitrate levels via a forced reduction in nitrogen fertilizer application would be borne mainly by producers. Consumers' surplus increases from a level of $332.0 to $345.6 million with a 40% reduction of nitrogen supply; producers' surplus de-

creases from $542.5 to $329.0 million. Although the environment might be improved by a policy of nitrate reduction, the burden obviously falls on the producers under these assumptions. The full welfare implications of such policy measures are complex and involve consideration of compensation principles of the Kaldor-Hicks variety. (For a brief discussion, see Merewitz and Sosnick.)

Summary and Conclusions

This paper has explored some of the impacts of energy cost increases and reduced supplies on the product mix of annual field crops and vegetables in California. The framework is comparative statics using a quadratic programming model. A demand matrix for some nine field crops and twenty-eight seasonal vegetables was entered directly into the objective function. No cross elasticities were considered. The procedure is computationally efficient given large capacity computer facilities.

Introduction of a yield variability coefficient as a measure of risk provided encouraging results for a base-period analysis, but further refinement is needed. The findings add emphasis to the work of Hazell and Scandizzo and Simmons and Pomerada as to the promise of introduction of risk into programming models.

The research findings indicate the adjustments that might be expected in the event of energy cost increases and quantitative restrictions. For example, imposition of energy restraints by subregion would appear to sharply reduce field crop acreage and to increase vegetable acreage. These results are conditional on the validity of the demand and cost specifications. Further, one might expect producers to make technological adjustments over time if this were a permanent change; also the full interregional competitive position of the region is not analyzed in this study.

The effect of increased energy costs, under the given demand specification, was to increase acreage and production of field crops and to decrease vegetable production and acreage. Additionally, restrictions on energy inputs such as nitrogen fertilizer and fuel (from 1972 levels) display effects on production, which, when taken in the aggregate, differ from those observed under the reduction of one input in isolation. For example, when nitrogen fertilizer supplies were cut back, acreage of field crops increased sharply but production still declined. The effect of a cutback in both fertilizer and fuel resulted in sharp reduction in production of both field crops and vegetables.

Such effects are, in part, dependent upon the availability of substitute inputs, such as land and water. Hence, an implication of such energy reductions is a substantial alteration of the derived demand for these resources, which may ultimately affect existing resource project repayment capacities and future feasibility of similar projects.

An attempt was made to isolate the welfare implications of energy changes on producers and consumers, but the use of ordinary rather than income-compensated demand functions and the inclusion of intermediate products are limitations to the analysis. If livestock products were in the model, feed grains would be a production input, and there would be no "consumers' " surplus associated with feed grains. The findings do, however, indicate directions of change that appear valid; namely, alternative energy change assumptions have strong differential effects on consumers and producers. This aspect should be considered in analyses of the impact on agriculture of any proposed energy program.

Interregional Structure of the U.S. Coal Economy

James D. Libbin and Michael D. Boehlje

A multiperiod spatial equilibrium model of the national coal economy is developed to evaluate future interregional shifts in coal production and the investment requirements and sequencing for exploitation of a nonrenewable, variable quality resource. The effects of alternative sulfur dioxide emission standards and demand growth projections on the location and type of coal production, the transportation industry, and capital markets are examined. The study concludes that the coal industry can expand through 1990, especially in Appalachia and the West, to meet both greatly increased demand and restrictive air quality standards at moderately increased cost.

Key words: air quality standards, coal, spatial equilibrium analysis.

The coal reserves of the United States represent the major proven sources of energy to satisfy increased energy demand during the next decade. Despite the great potential for nuclear power, further research must be undertaken to determine the long-term effects on the environment and the safety of this source. Domestic natural gas and petroleum reserves are being rapidly depleted, while uninterrupted flows from imports have become less certain. Additionally, the "fuels of the future" such as synthetic fuels and solar and geothermal power will probably not make significant contributions to energy supply before 1985 (Federal Energy Administration 1974, 1976).

The purpose of this paper is to analyze the impact of various policy decisions on the future development of the U.S. coal industry. Specifically, the results emphasize the regional reallocations of production necessary to meet projected growth in coal demand and the economic consequences for the coal industry of imposing alternative sulfur dioxide emission standards on coal-burning facilities. A description of the analytical model used in the analysis—a multiperiod interregional competition model—is presented in the next section. The empirical results, including a discussion of the competitive position of major coal-producing areas and an analysis of the effects of alternative sulfur dioxide emission standards, follow, along with concluding remarks and suggestions for further study.

The Analytical Framework

The coal mining and distribution complex is characterized by a depletable, heterogeneous product, an interregionally competitive structure, and demand functions that, because of governmental regulations on air quality and emissions, exhibit important quality as well as quantity dimensions. The time sequence and location of investment in new mines is a critical factor in the ability of the coal mining industry (as well as end-users of coal) to respond to expanded consumption. Consequently, a multiperiod, interregional competition model was formulated to evaluate the optimal adjustments required of various sectors of the U.S. coal industry (mining, washing, transportation, and consumption) to meet increased demand and more restrictive environmental standards. This normative interregional framework facilitated consideration of quality dimensions of the product (sulfur content and heating value), transportation costs and constraints, the efficient interregional structure of production, and investment requirements and sequencing for a nonrenewable resource.[1]

James D. Libbin is a research associate and Michael D. Boehlje is an associate professor of economics at Iowa State University.

Otte for their assistance with this research and to Richard Boisvert and two anonymous reviewers for their helpful suggestions on an earlier draft of this article.

[1] Although interregional competition (spatial equilibrium) mod-

The objective function of the model is designed to minimize the total discounted cost of mining, washing, and transporting coal, reclaiming strip-mined land, and constructing new mines, subject to constraints on mining equipment availability, known coal reserves, current mining capacity, sulfur dioxide emission standards, and the projected demand for coal. Cost minimization is justified on the basis of firm size, the competitive structure of the industry, and the behavior of utilities (the major users of steam coal) to obtain competitive bids.

Eighteen demand and twenty-one supply regions are specified with unique points of origin and destination (tables 1 and 2). Also shown in table 1 are the four major producing areas. Four time periods are specified: 1976–77, 1978–80, 1981–85, and 1986–90. New mine expansion before 1981 is limited to the number of new mines currently planned by the industry (Coal Age). The quantity of coal mined in any time period is limited to current mining capacity plus any new capacity added through subsequent investment; the total quantity of coal mined must not exceed available reserves. Coal washing is the only means of quality upgrading allowed, and rail is the only mode of transportation included.[2] Both surface and underground mining are included in the analysis, and mining of both thin and thick seams is considered in production regions with widely variable overburden and seam thickness characteristics.

els have been frequently used in agricultural economics (e.g., Heady and Srivastava, Takayama and Judge), their application to the energy and coal industries is relatively new (Nagarvala, Ferrell, and Olver; Schlottman; Federal Energy Administration 1974, 1976; LeBlanc) with the exception of early work by Henderson. Similarly, the utilization of intertemporal allocation models is not unique in agricultural economics research (Takayama and Judge, Swanson). However, few examples of empirical analyses that have combined intertemporal and interregional dimensions in an allocation model are available.

[2] Washing refers to the beneficiation processes generally used by the majority of eastern coal producers to rid the coal of dirt, rocks, other foreign matter, and some of the pyritic and sulfate forms of sulfur.

[a] Btu and sulfur content data are condensed from input data shown in Levins et al., pp. 73–93. Up to three quality levels, with unique Btu and sulfur content parameters, are designated for both run-of-mine and washed coals and for each producing region. A total of sixty-four distinct quality grades were programmed.
[b] Weighted average of all reserves.
[c] No coal washing allowed.

Table 2. Demand Regions and Regional Sulfur Dioxide Emission Standards

[d] Des Moines is the central point of six Iowa destinations.

Final demand for steam coal is specified exogenously by using demand estimates from the *Project Independence Report* (Federal Energy Administration 1974). The annual demand for coal in each region (measured in British thermal unit [Btu] content rather than tons) in 1976–77 is specified as equal to 1973 consumption; thereafter, demand is increased linearly to 130% of 1973 consumption by 1990. Additional analyses that assume 1990 consumption to be 150% of the 1973 base are also completed.[3]

Coal mining and washing costs vary by region, depending upon mining type, economies of size, seam thickness, overburden thickness, and reclamation requirements. Intraregionally, mining cost differentials depend on seam thickness and mining type. All costs are held constant throughout the time horizon of the model, as there is no basis for differential rates of change in cost by region, and uniform percentage increases in per unit costs will not affect the competitive position of the various producing regions. Future financial streams are discounted to reflect the fact that individuals and society have a positive time preference for money. The discount factor is calculated as a geometric weighted average of annual treasury bill rates to reflect a risk-free, pure time preference for money (Harris and Nehring).

One of the major environmental concerns with respect to the future development of coal is the level of sulfur dioxide emissions from burning. Four sets of sulfur dioxide emission standards are chosen for analysis: 5.0 pounds, 3.0 pounds, and 1.2 pounds of sulfur dioxide per million Btu in all regions, and a set of regional standards currently implemented or slated for future compliance by state legislatures (table 2). The 3.0 pound standard approximates the coal quality being burned by electricity generation plants and other users in the early 1970s, while the 5.0 pound standard represents a relaxation that some argue is nec-

[3] This exogenous specification of demand does not recognize the concept of price elasticity of demand. Recent studies indicate that the short-run price elasticity of demand generally falls within the limits of −0.123 to −0.259 (Appalachian Resources Project). Thus, projections of coal demand that ignore the price effects will overstate future consumption. Including price explicitly in the model would mandate a quadratic formulation, which would result in sacrifices in detail in other parts of the analysis. When this analysis was undertaken, *Project Independence* (Federal Energy Administration 1974) coal demand projections were the best and most recent available. Additionally, the 1973 edition of *Coal—Bituminous and Lignite* (U.S. Dep. Interior 1975) was the latest complete source of coal production and consumption data. Most recent editions indicate an increase in coal consumption of 8.7% between 1973 and 1975. Similarly, more recent Federal Energy Administration (1976) projections indicate demand increases should fall within a range of 59% to 109% by 1985, centering on a 72% increase. Comments on the implications of greater demand increases are presented later in this article. The interested reader should consult the *Project Independence* and *National Energy Outlook* reports (Federal Energy Administration 1974, 1976) for more detail on the demand growth assumptions.

essary to allow sufficient coal production to reach goals of energy independence. The regional standards represent a compromise between current operating procedures and more strict federal regulations, while the 1.2 pound standard represents the proposed federal Environmental Protection Agency guidelines. With respect to coal quality, sixty-four distinct quality levels are specified with up to six levels for each supply region. Of the total number of quality levels, thirty-seven are run-of-the-mine grade, while the remaining twenty-seven are washed grades of coal. Because the sulfur content of a particular region's coal determines the technical feasibility of use and the cost competitiveness of processing to reduce sulfur content, the quality of the resource is crucial in evaluating the competitive position of various production regions. An entire specification of all data and data sources, as well as additional discussion of the model structure, may be found in Levins et al.

The mathematical programming model used in the analysis can be summarized as

$$(1)\quad \min Z = \sum_i\sum_m\sum_r\sum_t \alpha_t a_{imrt} M_{imrt} + \sum_i\sum_m\sum_t \alpha_t b_{imt} N_{imt} + \sum_i\sum_s\sum_t \alpha_t c_{ist} P_{ist} + \sum_i\sum_j\sum_q\sum_t \alpha_t d_{ijt} T_{ijqt}$$

subject to mining restrictions:

$$(2)\quad \sum_r M_{imrt} \leq MC_{imt},$$

$$(3)\quad MC_{imt} = \beta_t MC_{im,t-1} + k_{im} N_{imt},$$

and

$$(4)\quad \sum_t M_{imrt} \leq R_{imr};$$

washing restrictions:

$$(5)\quad V_{irt} + \omega_{is} P_{ist} \leq \sum_m M_{imqt};$$

transportation restrictions:

$$(6)\quad \sum_j T_{ijqt} \leq V_{irt} + P_{ist};$$

demand and sulfur emission restrictions:

$$(7)\quad \sum_i\sum_q \psi_{iq} T_{ijqt} \geq D_{jt},$$

and

$$(8)\quad \sum_i\sum_q \frac{W_{iq}\psi_{iq} T_{ijqt}}{D_{jt}} \leq Y_{jt};$$

capital availability restrictions:

$$(9)\quad N_{imt} \leq N^*_{imt};$$

and additional restrictions:

$$(10)\quad M_{imrt}, P_{ist}, N_{imt}, T_{ijqt} \geq 0;$$

where Z is total cost; i is a particular supply region such that $1 \leq i \leq 21$; j is a particular demand region such that $1 \leq j \leq 18$; m is mining type such that $m = 1$ for surface mining and $m = 2$ for underground mining; q is a particular quality level encompassing both sulfur dioxide and Btu content, designations varying by regions such that $1 \leq q \leq 6$; r is a particular unprocessed quality level such that $r = \{q|1 \leq q \leq 3\}$; s is a particular processed quality level such that $s = \{q|4 \leq q \leq 6\}$; and t is a particular time period such that $1 \leq t \leq 4$. For the corresponding combinations of subscripts, the remaining variables are defined such that α_t is the discount factor in time period t (5.845% per year); a_{imrt} is mining plus reclamation cost per ton of coal; M_{imrt} is the quantity of coal mined; b_{imt} is the investment required to construct a new mine; N_{imt} is the number of new mines constructed; c_{ist} is the washing cost per ton of coal; P_{ist} is the quantity of coal washing; d_{ijt} is the cost of transporting one ton of coal; T_{ijqt} is the quantity of coal transported; MC_{imt} is the mining capacity of all existing mines; β_t is depletion factor (5% per year);[4] k_{im} is the capacity of a newly constructed mine; R_{imr} is the total available reserves; V_{irt} is the amount of coal transported without washing; ω_{is} is the inverse of the fractional weight recovery from washing coal; ψ_{iq} is the heating value of coal in Btu per ton; D_{jt} is the quantity of coal demanded measured in Btu; W_{iq} is the sulfur dioxide content contained in coal measured in pounds of sulfur dioxide per million Btu; Y_{jt} is the maximum allowable emissions for coal mixtures burned measured in pounds of sulfur dioxide per million Btu; and N^*_{imt} is the currently planned expansion of new mines.

The variable Z contains a complete accounting of the costs of extracting coal within the mine, investments in new mines, and the costs of washing and transporting coal and reclaiming strip-mined land. Constraints on the mining activities are identified by equations (2), (3) and (4), which require that gross mining activity can be no greater than the available mine capacity, specify that the mine capacity in any time period is equal to 95% of the mine capacity of the previous period plus any new mine construction, and require that the total mining activity not exceed the available reserves.

Washing constraints (5) require that the sum

[4] Both new and existing mines were assumed to have a useful life of twenty years. Five percent of existing mine capacity was depleted each year (β_t).

of unwashed coal shipments and original weight of washed coal shipments not exceed the mining activity within each supply region. The transportation constraints (6) specify that the sum of coal shipments from any supply region can be no greater than the sum of unwashed and washed coal produced in that region. Demand and sulfur emission constraints (7) and (8) insure that the sum of the amounts of coal transported into a particular demand region, multiplied by its relevant Btu value, shall not be less than the total demand in that region measured in Btu, while the total sulfur dioxide emissions shall not exceed the specified standard. The capital availability restrictions (9) limit new mine expansion, before 1981, to the number of new mines currently planned by the industry (Coal Age).

Empirical Results

The results of the regional sulfur standards are discussed first (assuming a 30% growth in demand by 1990), with the discussion that follows noting the adjustments in area market share and interregional shifts suggested by alternative sulfur dioxide emission standards.

Regional Sulfur Standards

Average annual coal production is summarized in table 3. Also shown is the actual tonnage and share of the U.S. market mined in the four major producing areas in 1973, the change from 1973 to 1990, and 1990 share of the U.S. market as predicted by the model. Figures 1 and 2 summarize the interregional coal shipments in two periods: 1978–80, the first period involving an increase in demand, and 1986–90, the long-run situation. Similar diagrams for 1976–77 and 1981–85 may be found in Levins et al.

The results indicate that few major adjustments in the location of production are needed to operate in the long run under the regional sulfur emission standards. Little change occurs in the market shares of each coal-producing area in 1986–90 compared with actual 1973 production. Thus, even with more restrictive sulfur standards in some regions than presently exist, the industry could expand sufficiently to meet the projected growth in demand. In all four of the major production areas, however, significant interregional reallocations are suggested, and some transporta-

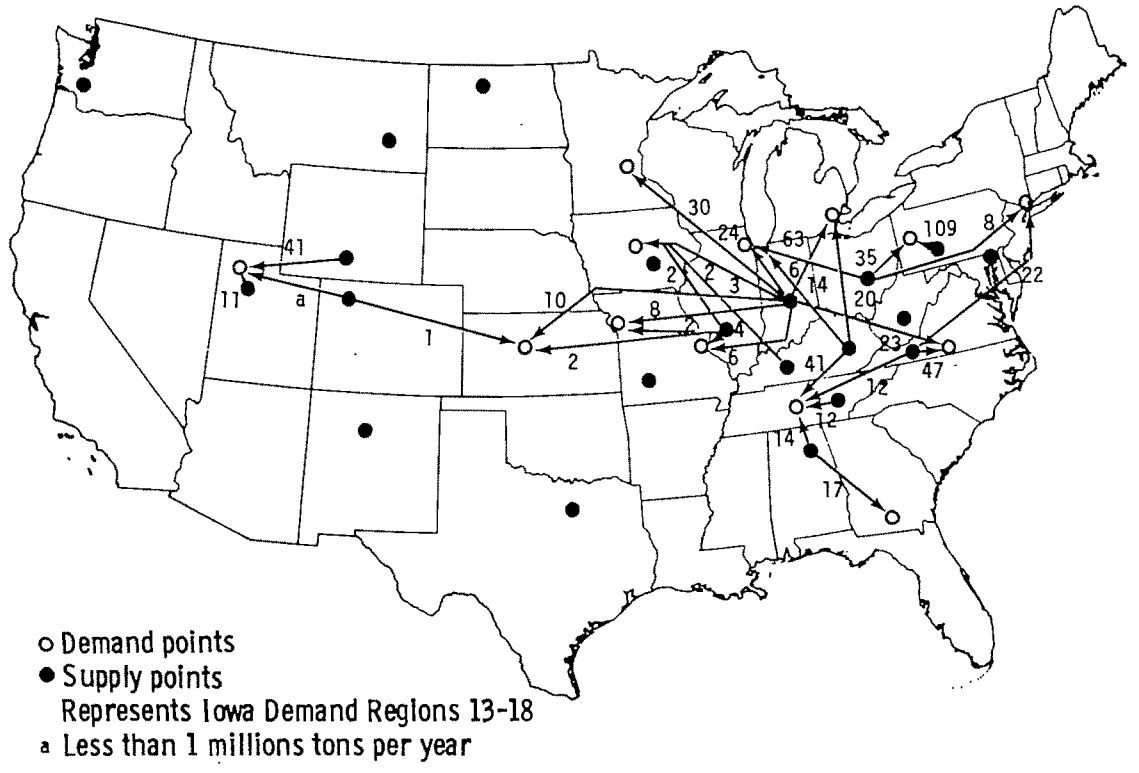

Figure 2. Coal shipments 1986–90 (million tons per year)

tion difficulties are foreseen. Much of this reallocation is necessary to use the higher quality reserves within each area. Other adjustments occur to exploit those geologic formations suitable to large-scale, low-cost mining and to take advantage of geographic locations with low transportation costs.[5]

In the West, the demand for Montana, Wyoming, and New Mexico coal is strong before 1981. After capital constraints are released, however, all the demand for western coal is supplied by Utah and Wyoming. Significant expansion occurs in the eastern coal-producing regions of Alabama-Georgia, Indiana, eastern Kentucky, Ohio, Tennessee, and Virginia after 1980. Although western mining costs are much lower than those in the eastern United States, the high transportation costs to move low Btu coal to eastern demand centers offsets the scale economies of western mining. Also Bureau of Mines washability and demonstrated reserve data indicate that adequate untapped reserves of eastern coal of sufficient quality are available for washing to meet the regional sulfur standards (Cavallaro, Johnston, and Deuerbrouck; U.S. Dep. Interior 1974). Without indicating the magnitude of shipments, shadow prices suggest that washing costs will have to be at least double those used in this analysis ($1.00 per ton) before western coal will be substituted for eastern washed coal after 1980.

Two important interregional shifts that reflect cost competition and resource availability interactions should also be noted. Indiana dominates its closest competitor, Illinois, in most scenarios analyzed. Indiana coal has both a lower sulfur and higher Btu content. When capital constraints are eliminated and new mines can be developed, Indiana production expands rapidly and Illinois production declines. Indiana depletes its reserves very rapidly before 1990, more rapidly than may be technically feasible or politically acceptable. Further analysis indicates that coal from eastern Kentucky and the West would probably substitute for Indiana coal if limits were placed on the rate of mine expansion in Indiana.

When long-run adjustments can be made, coal production in Virginia increases by 135%, and West Virginia production is reduced to almost zero. These dramatic shifts occur partly because of the specification of the supply and demand points in the model. The choice of demand points in the populous areas of the eastern United States results in consistently higher transportation costs to deliver West Virginia coal compared with coal from surrounding production regions. Shadow prices suggest that a relative change in total delivered costs (mining, processing, and transportation) of only $0.04 in favor of West Virginia would improve its long-run competitive position.

To produce the quantity of coal suggested by the model in the 1981–90 periods, a substantial number of new mines must be developed. Major mine construction activity is projected for Ohio, where 112.5 million tons of new annual strip-mine capacity are added in 1986–90. Other regions experiencing significant expansion in 1981–90 and the corresponding amounts of new annual strip capacity are Indiana, 105.0 million tons; Virginia, 62.3 million tons; eastern Kentucky, 47.6 million tons; and Pennsylvania, 20.4 million tons. The implications for land use and reclamation problems and conflicts in these regions are evident. Local land use policies and other externalities may tend to dampen the more dramatic expansion results. Only fifty underground mines with an average capacity of 930,000 tons per year are opened in the United States in 1981–90.

Because the results suggest concentration of production in regions with high quality reserves, serious coal transportation problems could occur. Although transportation constraints were not explicitly included in the model, most producing regions distribute their coal to numerous demand points, thus minimizing large shipments over single routes. Three regions, however, shipped amounts far in excess of actual 1973 shipments to specific demand points. All the Montana production is shipped into the North Central demand region, resulting in a flow five times greater than the 1973 movement. Also, 53% of Virginia's increased production goes into the Virginia-Carolina consumption area. The most serious transportation bottleneck is in the Midwest, where 60% of Ohio's 1986–90 production

[5] Solutions predicting zero or greatly reduced production for a particular region must be interpreted carefully. The model really suggests that these regions do not have a comparative advantage in coal production and expansion should not be encouraged under current conditions, not that all existing mines should be closed. Given the aggregative nature of an interregional competition model, two points of caution should be mentioned: (*a*) aggregation bias can distort results, and (*b*) individual firm behavior may differ from the "efficient" aggregate results. A firm with a large investment in a producing region may continue to produce as long as returns are sufficient to cover variable expenses.

(nearly 63 million tons per year) is shipped to Illinois-Indiana, compared with near zero shipments between these regions in 1973. The concentration of coal production in fewer regions will certainly aggravate already difficult transportation problems.

Alternative Sulfur Standards

One indication of the potential increase in the costs to the coal industry and to society in general of meeting increasingly strict emission standards for the period 1976–90 is the change in the value of the objective function as the sulfur standards are changed. The values of the objective function, when expressed in cents per million Btu, are 27.4¢, 27.8¢, 29.3¢, and 30.9¢ for the 5.0 pound, 3.0 pound, regional, and 1.2 pound standards, respectively. These figures are not of the magnitude expected for delivered market prices because they contain no allowance for profit and are in present-value terms. Costs increase by 1.2%, 5.5%, and 4.5% as standards are changed from 5.0 pounds to 3.0 pounds, 3.0 pounds to regional standards, and regional standards to 1.2 pounds. Thus, reducing sulfur emissions by 60% from 3.0 pounds to 1.2 pounds would require a cost increase of 11.4%.[6]

Part of the cost increase is caused by the regional concentration of production and the decline of the Midwest, with its geographic advantages, as a major producing region, thereby raising the total transportation bill. Also, more coal is washed with the more stringent sulfur standards, incurring an added cost of $1.00 for every ton washed. The greatest part of the cost increase is caused by the growth in high-cost underground mining, which accounts for 14.0%, 19.2%, 26.9%, and 31.2% of total production at the 5.0 pound, 3.0 pound, regional, and 1.2 pound standards, respectively. Thus, more restrictive sulfur standards discourage strip mining and favor expansion of underground mining. This effect is due primarily to a relatively higher concentration of low sulfur coal in the nation's underground reserves (U.S. Dep. Interior 1974).

Table 4 outlines the changes in coal production for the four major production areas, the four specified time periods, and the 5.0 pound, 3.0 pound, and 1.2 pound standards. As sulfur dioxide standards become more restrictive, those areas with lower sulfur content coal and competitive costs increase their share of the U.S. market dramatically.

The northern Appalachian area is least affected by changes in sulfur standards, producing 41.2%, 41.6%, 50.8%, and 41.6% of total U.S. coal consumption in the 1986–90 period under the 5.0 pound, 3.0 pound, regional, and 1.2 pound standards, respectively (compared with 47.1% in 1973). Northern Appalachia can

[6] An additional solution using a 1.5 pound standard indicates that a 50% reduction of emissions (from 3.0 pounds to 1.5 pounds) could be obtained for only a 6.5% cost increase.

Table 4. Average Annual Coal Production for Three Alternative Sulfur Standards

Area	Actual 1973 Production (1,000 Tons)	1973 Percentage of U.S. Market	Average Annual Production by Period				1986–90 Changes from 1973 (%)	1986–90 Percentage of U.S. Market
			1976–77	1978–80	1981–85	1986–90		
			1,000 Tons

West	56,589	9.8	86,926	92,547	60,656	52,542	−7.2	8.6
			1.2 Pound Sulfur Standard					
Northern Appalachia	273,384	47.1	264,162	256,433	237,149	254,818	−6.8	41.6
Southern Appalachia	101,415	17.5	109,681	108,504	196,776	224,559	121.4	36.6
Midwest	148,380	25.6	35,287	37,970	20,902	14,786	−90.0	2.4
West	56,589	9.8	92,293	134,190	111,200	118,943	110.2	19.4

be characterized as having a relatively large mine size, substantial surface and underground reserves, and relatively short haul routes to the major demand centers in the industrial Northeast and Midwest.

Southern Appalachia, with generally higher quality coal than northern Appalachia, faces locational disadvantages reflected in higher transportation costs as compared with either northern Appalachia or the Midwest. Therefore, when sulfur standards are relaxed and low sulfur coal does not have a comparative advantage, the southern Appalachian area produces far less than its 1973 U.S. market share of 17.5%. As sulfur standards become more restrictive and midwestern coal becomes unusable, the southern Appalachian area dramatically increases production in absolute as well as relative terms. Southern Appalachia produces 2.3%, 9.1%, 18.4%, and 36.6% of 1986–90 U.S. consumption under the 5.0 pound, 3.0 pound, regional, and 1.2 pound standards.

The Midwest has the most to lose if the more restrictive federal sulfur dioxide standards are adopted and enforced by state authorities. Because of the high sulfur content of its coal, the Midwest decreases production dramatically as standards are tightened, producing 48.9%, 40.7%, 22.1%, and 2.4% of 1986–90 consumption under 5.0 pound, 3.0 pound, regional, and 1.2 pound standards (the Midwest's market share in 1973 was 25.6%). The locational and transport advantages of the Midwest are irrelevant under tight sulfur standards because of the inability to sufficiently reduce the sulfur content of its coals with current washing technology.

The West is an important source of future coal production in the view of many analysts. The results of this study, however, are less encouraging for the development of western coal than past reports. Although the West does increase production as sulfur standards are tightened, the long distances (and resulting high transportation costs) coupled with low Btu content discourage the use of the lower sulfur western coals in favor of eastern underground coals. The West produces 7.6%, 8.6%, 8.7%, and 19.4% of 1986–90 U.S. consumption under 5.0 pound, 3.0 pound, regional, and 1.2 pound sulfur standards. Even though western production nearly doubles from 9.8% of the 1973 market to 19.4% of 1990 consumption, under the 1.2 pound standard, no western coal is shipped to points east of the Mississippi River.

The effect of increasingly strict sulfur emission standards is dramatically illustrated by changes in the production of low- and high-quality coal in Kentucky, a state that overlays two major production areas, southern Appalachia and the Midwest. Under the relaxed 5.0 pound sulfur standard, western Kentucky shows a 33% increase in production from 197[illegible] to 1990. The more strict regional and 1.2 pound standards make it too costly to use western Kentucky, low-quality coal even for blending. On the other hand, eastern Kentucky's more expensive, higher quality coal plays a major role in meeting the national coal demand under the regional and 1.2 pound standards but is an insignificant source under the 5.0 pound standard.

The shifts in production within each of the four major producing areas as sulfur standards are varied should also be recognized. The results indicate that in northern Appalachia the major suppliers of coal for all emission standards are Virginia, Ohio, and Pennsylvania. Ohio and Pennsylvania combined produce nearly the same amount of coal under each of the four sulfur standards, but Ohio production declines and Pennsylvania production increases as standards become more restrictive. In the southern Appalachian area, Alabama-Georgia and eastern Kentucky are major coal producers in all situations except with the 5.0 pound and 3.0 pound standards and western Kentucky under the 5.0 pound standards. Western coal production is concentrated in Montana, Utah, and Wyoming. Most of the interregional shifts are caused by the relative availability of various qualities of coal and the geographic advantages that translate into low transportation costs.

Processing capacity does not seem to present any serious problems for the coal industry before 1980 for even the restrictive 1.2 pound standard but may be a serious impediment to growth after that year if new technology (gasification or stack gas scrubbing) is not available to efficiently reduce the sulfur content of coal. Potential transportation problems discussed earlier are aggravated even more by the increasingly strict sulfur standards because a larger quantity of the nation's coal must come from those few production regions with low sulfur reserves.

For the coal-mining industry to expand production into higher quality reserves, capital outlays of nearly $5.4 billion will be needed in 1981–85 for mining equipment alone, plus $2.1 billion more in 1986–90 to meet increased de-

mand assuming the regional sulfur standards. An additional $923 and $201 million will be needed in 1981–85 and 1986–90, respectively, to comply with the federal 1.2 pound sulfur standards.

Alternative Rates of Demand Growth

The demand growth assumed for the analysis thus far calls for a 30% increase in coal consumption by 1990 over 1973 levels. A second demand growth assumption, a 50% increase by 1990, produces results similar to the 30% growth rate. Each major producing area mined more coal to meet the larger demand, but the impact on the market share of each area varies according to sulfur standard assumption. As evidenced by the data of table 5, southern Appalachia increases its percentage share of the U.S. market dramatically under the higher demand growth rate, especially with the more restrictive sulfur standards. Most of southern Appalachia's gain comes at the expense of northern Appalachia. The West consistently gains in market share with the higher growth rate in demand, although the increases are less dramatic than for southern Appalachia. The West generally expands into markets previously held by the Midwest. The regional impacts of demand growth rate are generally greatest for the Appalachian areas under the regional and 1.2 pound sulfur standards, while the greatest impacts occur under the 3.0 pound and regional sulfur standards for the West and Midwest.

The cost of delivered coal and the amount of coal washed changes only slightly between the two demand assumptions, although the higher growth rate causes a 3% increase in the proportionate share of underground mining and a 28% increase in total capital investment needs.

Conclusions

The results of this analysis indicate that adequate supplies of high-quality minable coal are available within the United States to allow both an increase in coal demand and further tightening of sulfur dioxide emission standards. In short, the coal-mining industry is capable of responding to demands for both energy independence and environmental protection. These goals, however, cannot be reached without complementary response from labor unions, the capital equipment industry, and the transportation industry, nor without some added costs that most certainly will be passed on to the consumer.

Additional costs will be incurred in producing a larger quantity of higher quality coal. This analysis indicates that most of the cost increases to 1990 are associated with increased demand rather than more restrictive sulfur standards. With constant (1973) demand and emission standards approximating current practice (3.0 pound standard), the discounted cost of delivered coal is 24.6¢ per million Btu. A cost increase of 12.9% is suggested to increase demand by 30% from 1973 to 1990. A further cost increase of only 5.5% is needed to change from the 3.0 pound to the regional standards or of 11.4% to change from 3.0 pounds to 1.2 pounds. However, an added increase of only 6.5% is suggested for a change from 3.0 pound standards to a compromise 1.5 pound standard.

Significant changes in the regional location of coal production are suggested with changes in sulfur dioxide emission standards. The Midwest increases production dramatically under the relaxed sulfur standards, while southern Appalachia increases its market share under more restrictive standards. The amount of coal supplied by northern Appalachia changes very little as sulfur standards are varied. Although the West does expand production as sulfur standards are tightened, western coal is never shipped to points east of the Mississippi River.

Increased strip-mining activity is also sug-

Table 5. 1986–90 Percentage of U.S. Market for the Four Major Producing Areas

	Sulfur Standards							
	5.0 Pound		3.0 Pound		Regional		1.2 Pound	
	Demand Growth							
Region	30%	50%	30%	50%	30%	50%	30%	50%
Northern Appalachia	41.2	41.2	41.6	41.4	50.8	42.5	41.6	36.0
Southern Appalachia	2.3	4.7	9.1	16.5	18.4	26.9	36.6	42.6
Midwest	48.9	46.2	40.7	31.9	22.1	18.9	2.4	1.8
West	7.6	7.9	8.6	10.2	8.7	12.5	19.4	19.6

gested, as the amount of coal strip-mined is 86.0%, 81.8%, 73.1%, and 68.8% of total production under 5.0 pound, 3.0 pound, regional, and 1.2 pound sulfur standards, compared with 46.8% in 1973. Although reclamation of strip-mined land would seem to be a more serious problem in the future, the environmental and agricultural impact of increased strip mining could be reduced by more restrictive sulfur dioxide emission standards.

The results of this analysis are generally consistent with other studies of the coal industry, particularly those completed by Schlottman; Nagarvala, Ferrell, and Olver; and the Federal Energy Administration (1976). Although each analysis differs somewhat in approach and input data specifications, most confirm that eastern coal is available to meet much of the demand increase projected for the intermediate term future and that western coal will become a larger and very important, although not exclusive, producer of high quality coal in the longer run.

Finally, this modeling effort must be evaluated with due consideration to the underlying assumptions of the methodology, the problems associated with a large data set, and the level of technology and efficiency included in the model. Some of the more important current and future technologies not incorporated in the analysis include barge and Great Lakes shipping, on-site electricity generation, gasification, and slurry transportation. Also, coal blending was assumed possible, rail transport capacity was assumed unlimited, and metallurgical coal reserves and demand were not separated from steam coal. Thus, further research is needed and underway to analyze the impact of alternative transportation modes and capacities, differential reclamation policies, the social cost of and labor union resistance to displacement of miners from one region to another, disaggregation between steam and metallurgical coal markets, processing technologies, further disaggregation of supply and demand regions, regionalized demand growth projections, export and import balances, and future development of the industry beyond 1990 to the year 2020.

Response Time and the Location of Emergency Medical Facilities in Rural Areas: A Case Study

S. G. Daberkow and G. A. King

A framework to analyze the delivery of emergency medical care in northern California is proposed. Using a branch and bound algorithm, the most efficient (least-cost) size, number, and location of emergency medical facilities is found subject to a given level of demand and a measure of effectiveness (response time). The current spatial pattern of emergency medical service (EMS) facilities is compared with the most efficient spatial pattern. Due to the sparse distribution of the study area population, some individual EMS facilities are not economically viable given the current revenue structure. Funding alternatives for EMS, including volunteer service, are discussed.

Key words: branch and bound algorithm, emergency medical service, northern California, rural areas.

A goal often espoused for rural development is to reduce the disparities between urban and rural areas in provision of goods and services such as health care and schools (Jones and Gessaman). Since rural areas have small population clusters distributed over a wide area, they may lack economies of scale in facilities found in urban areas. The private sector may be hard pressed to deliver services of high quality due to the costs involved. If public funds are to be used to lower costs, policy makers at all levels of government need information that enables them to allocate resources to reach these goals most efficiently. This study illustrates how economic analysis may assist in the planning process for the delivery of a particular service—emergency medical service (EMS)—in a rural environment.

Objectives

Willemain has presented the goals of an EMS system in terms readily recognizable by economists:

> The goals of the EMS system are to prevent death, disability and suffering in persons with injury or acute illness. The allocation of public resources should be systematically directed to these ends; ideally, the EMS planner should be able to assess the impact of proposed combinations of money, people, facilities and equipment in terms of death, disability and suffering. In other words, the best planning requires input-output relationships linking resource allocations to patient outcomes (p. 4).

Unfortunately, the input-output relationships are not available. Health planners do not currently have available data concerning the effects of various combinations of EMS resources upon the mortality and morbidity of the population under consideration. Thus, this study concentrates on the location of EMS resources rather than the relation between these resources and death, disability, and suffering. The empirical results should be useful to health planners and policy makers who must deal with standards for EMS delivery and the costs associated with those standards.

Two basic assumptions are made: health services should be provided to all persons needing these services, and health services should be provided as efficiently (least-cost) as possible (Cordes). In addition, an EMS system should account for nonresidents in an area, the costs of alternative EMS systems, the size, number, and location of EMS facilities, and a measure of effectiveness.

S. G. Daberkow is an agricultural economist with the Economic Research Service, U.S. Department of Agriculture, and G. A. King is a professor of agricultural economics, University of California, Davis.

Giannini Foundation Research Paper No. 445. This article is developed from research supported by the Economic Research Service, Economic Development Division, U.S. Department of Agriculture. The authors wish to acknowledge John Kushman, Charles Moore, Robert Coltrane, Fred Hines, and Sam Cordes for their constructive criticism.

Two standards of effectiveness are response time and service time. Response time is time elapsed from the dispatch of an ambulance and the arrival of an emergency vehicle at the emergency scene. Service time is the time from the dispatch of the ambulance to the arrival of the patient at a hospital. The former standard emphasizes a rapid response of vehicle and trained crew to an emergency situation, whereas the latter standard accentuates the rapid transport of the patient to a more fully equipped hospital emergency room. This study incorporates these standards into the analysis while illustrating the application of a location algorithm (branch and bound programming) that aids in determining the optimal size, number, and location of facilities.[1]

The major objectives of this research are: (*a*) to minimize total costs of providing ambulance service under different standards of effectiveness; (*b*) to determine the trade-off between total costs and different standards of effectiveness; and (*c*) to analyze the financial feasibility of providing EMS as standards of effectiveness and EMS facility usage change.

A specific intent of this case study is to analyze EMS delivery in a rural environment. The study area is the Upper Sacramento Valley of northern California. The sparsely settled mountainous areas surrounding the small- and medium-sized population clusters in the foothills and valley are typical of many rural population distributions.

Operational Model

Background literature on the location of firms and/or agricultural production is quite extensive. The theoretical work of Lefeber, Isard, Kuenne, and Takayama and Judge should be acknowledged as well as a large number of applied studies (see Weinschenck, Henrichsoneyer, and Aldinger). More recent work has involved the use of location algorithms in the public sector (Miller and King; Revelle, Marks, and Liebman). Examples include the work of Hardy, Marshall, and Faris on the placement of medical facilities and Holland and Baritelle on location pattern of schools.

A relatively new class of algorithms, known as tree-searching or combinational programming, can be applied to location problems exhibiting certain characteristics.[2] Typically, these problems minimize only assembly and processing or processing and distribution costs where supply or demand, respectively, is predetermined. These models can be used for locating commodity processing facilities, but their primary use has been with warehouses, hospitals, clinics, schools, airports, transport terminals, police stations, and fire stations (e.g., Chaiken and Larson). If the processing facilities' total cost function is linear with a positive intercept, the problem becomes the classic fixed charges transportation problem (Hadley, p. 136; Scott, p. 128). Such a function implies declining average facility cost.

Additional constraints (such as travel time or distance) are often added to these models to meet various goals defined by a planning body concerned with the provisions of the particular good or service. However, such a system of facilities may no longer be economically self-supporting solely by user fees (i.e., a tax-supported system may be necessary). The reader is referred to Hirsch for a comprehensive discussion of demand and supply aspects of public goods and services.

Algorithms used to solve the above problems range from complete enumeration, such as the Stollsteimer model, to the more systematic examination of a combinatorial tree.[3] The latter approach includes the branch and bound algorithm, backtrack programming, and discrete dynamic programming (see Scott, chap. 2, for an introduction to these techniques). Manne utilizes dynamic programming to solve the location-allocation problem "based on the fact that the total cost of processing and distribution form a hypercube with regard to all possible combinations of locations" (Weinschenck, Henrichsoneyer, and Aldinger, p. 47). This technique is also known as

[1] A reviewer correctly pointed out that the algorithm only considers facility total costs and not declining average costs, which are associated with economies of scale. However, since the facilities are assumed to be uncapacitated (i.e., an ambulance will always be available at a potential facility), the total cost curve is of a long-run nature. This curve is assumed to be linear with a positive intercept; hence, increased usage of a facility implies declining average cost. Size of facility is defined in terms of number of ambulance calls, not in terms of the number of ambulances at that facility.

[2] These problems are sometimes called location-allocation problems. They have the following general structure (Scott, p. 118): "Suppose that there are given (*a*) a set of *n* points distributed in the plane; (*b*) a numerical weight to be attached to each point; and (*c*) a set of *m* indivisible centroids without predetermined locations; then the location-allocation problem in its most general form is to find locations for the *m* centroids and an allocation of each point, or fraction of a point, to some centroid so as to optimize an objective function." In this study, *m*, the number of centroids or facilities, is also part of the solution rather than given.

[3] Integer programming is another alternative, but its application seems limited to small, well-behaved problems.

steepest-ascent-one-point-move algorithm, or SAOPMA. Manne notes, however, that the algorithm may give a local optimum rather than global. An example of backtrack programming used as a location algorithm is not known; however, the solution technique is similar to that of branch and bound programming, which is utilized in this study. All of these techniques can solve very general location problems including those with some nonlinearities. However, their major drawback has been their inability to handle large problems, either because of computer storage requirements or solution times.[4]

This study utilizes a modified branch and bound algorithm to solve the fixed charges transportation problem noted above. The algorithm was proposed by Efroymson and Ray. Khumawala has improved the efficiency of the program. This algorithm was found to be operational for moderately large location problems on the CDC 7600 computer, located at the Lawrence Laboratory, Berkeley, California. (Extensive testing of the capacity and time requirements of the algorithm is reported by Khumawala.) The basic idea is to solve a sequence of linear programming problems (not necessarily meeting the integer restriction) that give progressively improved lower bounds on the value of the objective function of the mixed integer problem. The algorithm terminates when the lowest value for an integer solution is reached.

The mathematical model is as follows:

$$(1) \qquad \min Z = \sum_{i \in N_j} \sum_{j=1}^{n} C_{ij} X_{ij} + \sum_{i=1}^{m} f_i y_i$$

subject to

$$(2) \qquad \sum_{i \in N_j} X_{ij} = 1, \text{ for } j = 1, 2, \ldots, n,$$

$$(3) \qquad 0 \leq \sum_{j \in P_i} X_{ij} \leq n_i y_i, \text{ for } i = 1, 2, \ldots, m,$$

and

$$(4) \qquad y_i = 0, 1, \text{ for } i = 1, 2, \ldots, m,$$

where C_{ij} is the total cost of satisfying the entire demand for EMS services from demand point j from a facility at i (i.e., $C_{ij}=(t_{ij} + \lambda_i)D_j$); t_{ij} is the dollar cost per patient per mile multiplied by miles from i to j; λ_i is the cost per patient that is independent of distance (e.g., linen supplies, equipment use, etc.); D_j is the demand for EMS (ambulance service) at demand point j (patients); X_{ij} is the fraction of the demand at point j that is met by a facility at i; f_i is the fixed charge for establishing and maintaining a facility at i; y_i equals 1 if a facility is established at i and 0 if not; n is the total number of demand points; m is the total number of potential EMS facility sites; P_i is the set of demand points that can be served by a facility at i; n_i is the number of elements in P_i; and N_j is the set of EMS facilities that can serve demand point j. The objective function (equation (1)) indicates the mixed integer nature of the problem, since X_{ij} is continuous and y_i is a binary variable. Equation (2) ensures that total demand at each demand point is exactly satisfied, while equation (3) ensures that a facility i is open before it can serve demand point j.

Demand and Cost Estimates

One of the primary objectives of EMS health planners is to account for resident and also nonresident need for such services. Jeffers, Bognanno, and Bartlet define need as "that quantity of medical services which expert medical opinion believes ought to be consumed over a relevant time period in order for its members to remain or become as 'healthy' as is permitted by existing medical knowledge" (p. 46).

Economists tend to consider demand for goods and services as being a function of prices and income. Thus, demand is usually constrained to a greater extent than is need. However, in true life-threatening situations where medical attention is not postponable, the influences of prices and ability to pay diminish. Emergency ambulance service is considered to be price and income inelastic, and the aggregate demand for such services is related to such variables as population, type of occupation, and the like.

Measures of need and demand are difficult to obtain. For example, the medical profession does not give an unequivocal definition of need that can be translated into an operational standard for response time. Further, available data are for actual usage that may be

[4] Another category of solution algorithms, not discussed here, is known as heuristic methods and defined as (Scott, p. 39): "algorithms [that] represent sets of rules which produce solutions to given problems, but which do not necessarily produce the best possible solutions." The interested reader should consult the bibliography of Scott. A recent example of such an algorithm in the *Journal* is given by Hardy and Grissom.

influenced by availability of services rather than a pure demand or need concept. Also, the data generally reflect total ambulance services including both emergency and nonemergency calls. Discretionary use of ambulance services such as routine transfers is most likely influenced by price, income, or type of insurance coverage. Previous studies, such as by Aldrich, Hisserich, and Lave, have found some price elasticity in the demand for ambulance services, but this may reflect nonemergency response.

Annual and Peak Month Demands

The "demand" for ambulance services by the residential population was estimated to be 29.5 calls per 1,000 population per year. This estimate, which includes emergency as well as nonemergency calls (t-value = 14.8), is based on regression analysis using data from the California Department of Transportation's *1968 Ambulance Survey* of thirty-six counties with less than 125,000 population (a comparable figure based on an analysis of all counties in California is 48.5 calls per 1,000 population, which apparently reflects the higher urban use pattern). The counties with less than 125,000 were assumed to represent the demand conditions of California's rural counties.

Northern California experiences a large seasonal influx of tourists, sportsmen, campers, and others seeking outdoor recreation. In addition, Interstate 5 serves as a major transportation artery for west coast travel, adding transients to the potential demand for emergency services. Data on transient population were estimated for all major highways in the area based on reports of traffic flow published by the California Business and Transportation Agency. Recreation use data are available from the U.S. Forest Service, California State Parks and Recreation Department, U.S. Department of Interior, the National Park Service, and the Pacific Gas and Electric Company (see Daberkow for data sources). Private recreation sites are not included, but second home tracts in U.S. forests are included.

The above annual demand estimates are expressed in terms of calls per resident. Some of these calls may have been by nonresidents, and therefore the number of calls on a per resident basis may be overstated. The transient population estimates derived from the above sources are utilized to give a demand for EMS based on resident plus nonresident population. Transients, by definition, are in or near a given point for a short (less than a year) time. Therefore, estimates are expressed in terms of visitor-days on a monthly basis for various points throughout the study area. Combining visitor-days with resident-days gives population-days, which is one indication of the monthly distribution of population concentration at selected points.[5] August is the peak concentration month for this area. Regression analysis, using counties as observation units, reveals an estimate of 0.435 ambulance calls per 1,000 population-days.

Demand Points and Potential Facility Sites

The study area population, which is dispersed over approximately 13,000 square miles, is represented by seventy-two demand points (see figure 1). The decision for inclusion of nineteen of the seventy-two demand points was clear cut. The population of these cities, reported by the 1970 census, ranges from 1,115 to 32,818 (U.S. Dep. Commerce). The population for enumeration districts nearby these cities is also represented by that demand point. In aggregate, these nineteen demand points include 81% of the study area population. Selection of fifty-three other points was based on two other sources of information—the California Division of Highways listing of rural and urban places by population category and the U.S. Post Office listing of zip code areas.

The demand points used in this study, therefore, represent a wide range of population distributions within varying geographic shapes. The geographic areas represented by the demand points vary in size (i.e., square miles), population, and concentration of population about the point.[6]

Thirty-two of the seventy-two demand points were selected for potential facility loca-

[5] A visitor-day is defined as one visitor at a particular site for twelve hours. A resident-day equals two visitor-days, since a resident is assumed to remain near a given point for twenty-four hours per day.

[6] Density (people per square mile) is not an adequate measure of the population distribution. For example, a large population cluster in a large area may have the same density as a small area with a small population. However, if the former area has its population concentrated near the demand point whereas the latter population is scattered, population density is a poor index of dispersion. A more desirable variable is the proportion of population within, say, a mile radius of the demand point. For nineteen cities, about 71% of the assigned population is within the city limits. No such information is known for the other demand points, since reliable census data are available only for places and cities larger than 1,500 population.

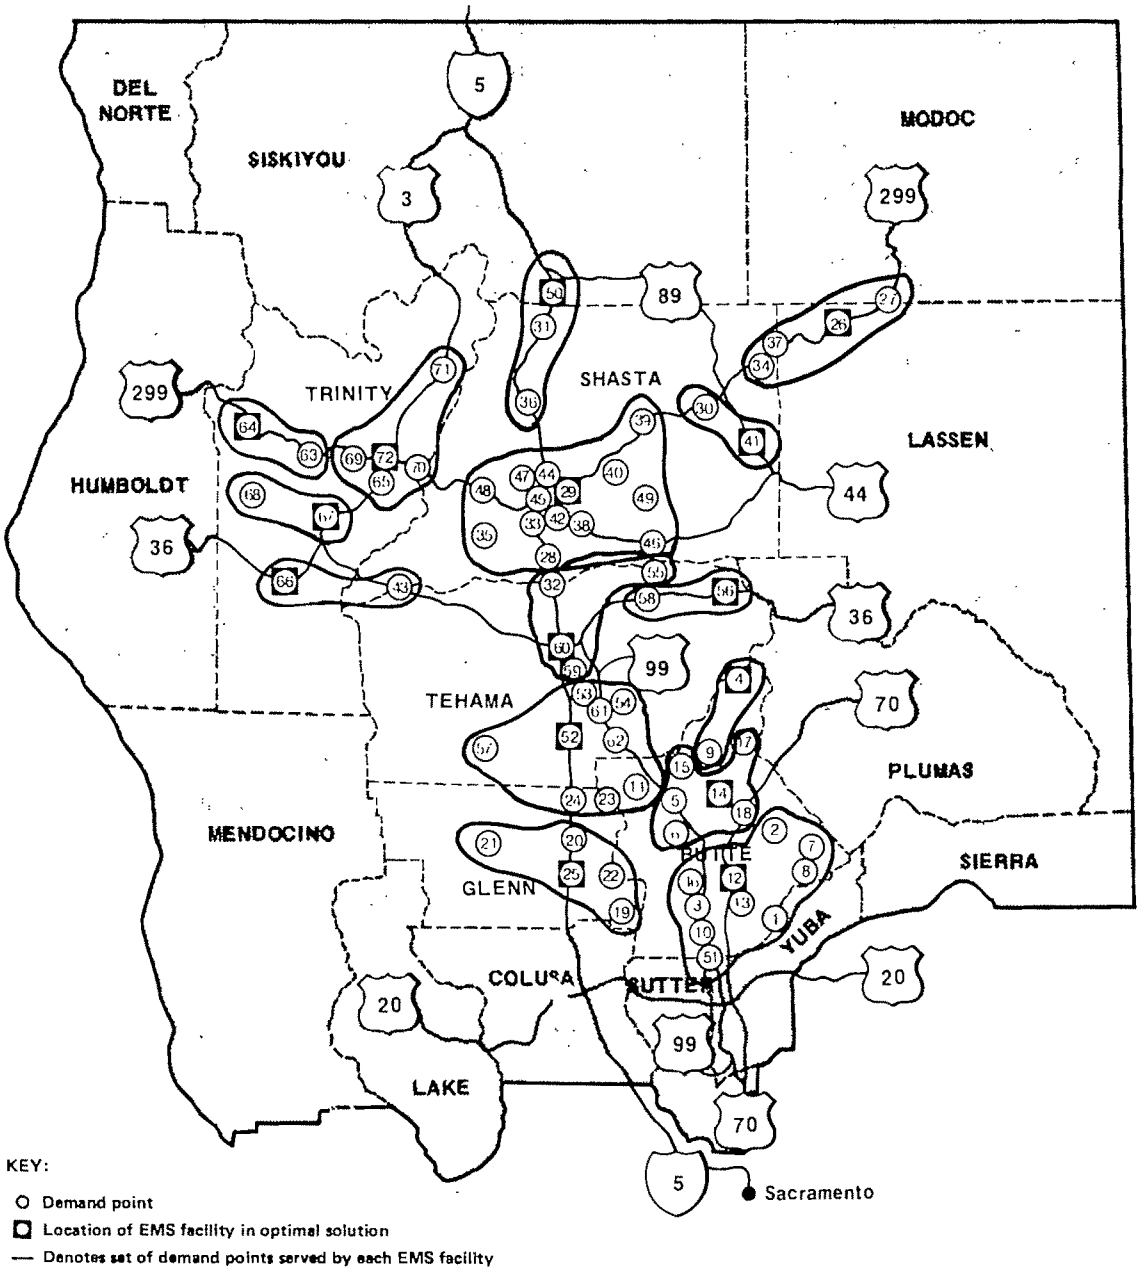

Figure 1. Facilities and demand points associated with those facilities using the forty-minute response time standard (optimal system)

tions. These sites were selected on the basis of two general guidelines. First, fifteen cities currently served by an EMS facility are included. The remaining seventeen potential sites were selected by inspection of the spatial dispersion of demand points and the associated travel time to existing facilities. In these more remote areas, a point could be designated a potential facility site regardless of its population size in order to meet the largest response time standard (i.e., one hour).

EMS Cost Function

The basis of cost estimates for ambulances is the National Highway Safety Bureau report by Dunlop and Associates. This points out the high costs of providing quality emergency

services for rural areas that generate relatively few calls and require long travel times. Many rural areas have responded to these high costs by initiating a lower quality volunteer EMS facility, lowering per call costs. Since population density varies widely in the study area, average costs per call also are expected to vary accordingly even with a volunteer EMS facility.

The question of economies of scale essentially refers to a planning curve for facilities of varying designed capacity, i.e., one, two, or more ambulances per facility. For the study area, the one ambulance facility appears feasible due to the low demand for ambulance calls.[7] However, the nature of fixed cost for the facility must be considered. It has two aspects. The first is the conventional aspect that French, Sammet, and Bressler describe as "fixed base (that) represents the long-run average rate of return above variable costs that are required to maintain and replace the capital goods" (p. 572). Capital goods would be the ambulance and related facilities. The second aspect of "fixed cost" for a twenty-four-hour ambulance facility is the crew needed if the facility is opened. Of course, a volunteer crew requires a substantially smaller "fixed cost" outlay.

The annual cost function for a full-time EMS crew and facility is based on an update of the Dunlap and Associates study. The estimated cost of a fully staffed, twenty-four-hour per day ambulance service is $70,000 plus $10 per call plus 10¢ per mile of response distance. The $10 per call reflects variable costs (e.g., oxygen, splints, linens, etc.) independent of fixed costs. Fixed costs are much lower for a volunteer EMS crew. For this study, the annual costs of a volunteer facility are estimated to be $6,500 (fixed cost) plus $10 per call (variable costs) plus 10¢ per mile of response distance.

[7] This model implicitly assumes an ambulance will always be available at a potential facility, thereby neglecting probabilistic aspects of ambulance call arrival rates and ambulance service times. Using queuing theory notation, this implies an M/M/∞ or M/G/∞ system (Wagner, pp. 865–66). The facilities are commonly assumed to be uncapacitated, and a postoptimization analysis determines the number of ambulances necessary at each facility to keep expected response time below a given standard. (See Bell and Allen for a discussion of the number of ambulances necessary at a given location.) An M/G/∞ queuing model, for a one-ambulance facility servicing 2,012 calls per year (the largest number reported in this study), using a mean monthly arrival rate and having a one-hour average service time, would exhibit a probability of 0.19 for a call having to wait.

Location of Facilities

Currently, there are fifteen EMS locations serving the area. The present system is compared with optimal locations for given levels of demand and response and service time standards. Response time refers to the time between the notification of an emergency and the arrival of an ambulance at the scene. Emphasis is given to the trade-off in total costs and percentage of population served as the response time standard is increased from thirteen minutes, a standard often promulgated for an urban area by health planners, to sixty-seven minutes.[8] The latter is considered an upper limit to effective response time.

Response Time Standards

Given the present system with fifteen EMS facilities and a thirteen-minute response time, forty-two of the seventy-two demand points cannot be served within that time standard.[9] These points represent about 25% of the population of the entire area. As the time standard is increased by increments of approximately thirteen minutes, the number of sites needed is reduced until, at a sixty-seven minute response time, only eight sites could serve the entire population at a cost of about 57% of that for the simulated thirteen-minute situation. Results for these and other response times are shown in table 1 for the present system.

An optimal location of facilities under these same response time standards and demand conditions is also given in table 1. To meet the thirteen-minute standard, EMS facilities would have to be located at thirty-one of the thirty-two potential sites (see table 1). However, twenty-two demand points still would not be served under this time constraint, or about 14% of the area population. One should note that, in order to serve 100% of the population within thirteen minutes, more than thirty-two facility sites are required.

[8] The response times were selected to correspond to the time an ambulance traveling an average of 45 miles per hour would require to travel 10, 20, 30, 40, and 50 miles, respectively.

[9] The algorithm requires that all demand points be served within at least sixty-seven minutes. When a smaller response time is imposed, not all demand points can be reached within that time. Of course, all demand points could be served within a given time standard if an EMS facility could be established at each demand point. However, this was fiscally infeasible; therefore, only thirty-two of the demand points were allowed to be potential facility sites.

Table 1. Response Time Standards: Comparison of Selected Parameters for the Optimal and Present Location Patterns of EMS Facilities (Annual Demand)

Response Time Standard (Minutes)	Number of Facilities	Total Annual Cost (Mil. $)	Demand Points Not Served	Percentage of Total Population Served
		Optimal System		
13	31	2.244	22	86.2
27	22	1.615	11	97.7
40	15	1.129	1	99.8
53	9	0.709	0	100.0
67	8	0.640	0	100.0
		Present System		
13	15	1.125	42	75.1
27	14	1.055	21	95.5
40	12	0.916	9	98.4
53	9	0.707	1	99.9
67	8	0.641	0	100.0

The trade-off between response time standards and system cost is shown in figure 2, where costs drop sharply as the number of facilities decrease and response time increases. The percentage of the population served, however, increases with decreases in response time. For a thirteen-minute response, 86% of the population is served, but for a twenty-seven minute response time with twenty-two facilities, about 98% of the population is served. The location pattern of EMS facilities and demand points served by those facilities for the forty-minute response time is given in figure 1.

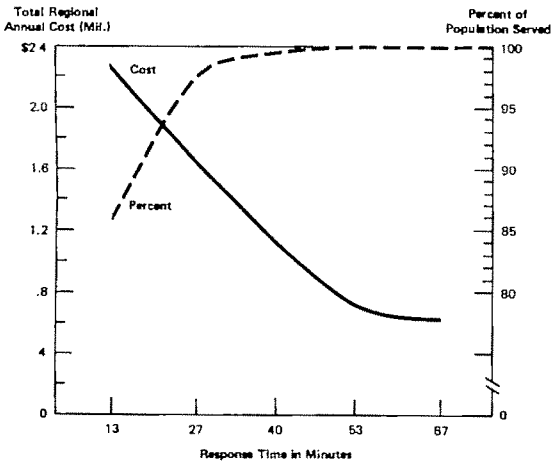

Figure 2. Relation between response time, total regional cost, and percentage of population served within various response times

The standards promulgated in the 1974 California state plan for Emergency Medical Services delivery suggest that 90% of the population for low density areas should be within thirty minutes of an EMS facility (California State Dep. Health). The twenty-seven-minute response time standard meets these criteria. The total cost of this system is $1.6 million. However, this system does not account for nonresident needs, which are discussed next.

Peak EMS demand occurs during the summer months, particularly in August. If the goal of the EMS system is to locate permanent facilities to meet the peak month demand of residents and nonresidents at minimum cost, the analysis must be modified. The approach is to estimate the number of population-days for transient population associated with the various demand points based on estimated traffic flows and visits to parks and forests. Demand for EMS is assumed to be a function of the number of population-days at each demand point.

The resulting location of facilities did not change substantially from that given previously. The annual costs are slightly higher due to travel costs for more patients. Also, there are slight reductions in the percentage of population served with given response time standards. This is due to the use of remote recreation areas by nonresidents.

Service Time Standards

Service time is defined as the total time between notification of an accident and delivery of the patient to the nearest hospital. Service standards are set at twice the corresponding response time standards to evaluate the trade-off between costs and service time. Since the general results are similar to those presented for response time, these will not, in the interest of brevity, be presented. There are differences, however, in the location of facilities for the service and response time standards. Given locations of hospitals, the service time model locates EMS facilities so as to minimize backtracking. Figure 1 indicates the location (numbers in parentheses) of the following study area hospitals: Chico (5), Paradise (14), Oroville (12), Gridley (10), Willows (25), Redding (45), Fall River Mills (34), Red Bluff (60), Corning (52), and Weaverville (72).

Financial Feasibility of Individual Facilities

The previous analysis provides aggregate costs of a regionwide EMS system with given response and service time standards. To answer the question of the economic feasibility of the individual facilities, the forty-minute response time model with annual resident demand is selected. (Other response times can be analyzed similarly; however, the forty-minute response time adequately illustrates the economic concepts.) Here, fifteen sites are found in the optimal solution. We have shown how costs vary under different response times, so costs and revenues for each facility are developed next.

Health planning officials indicate that private ambulance operations in the study area commonly charge a basic amount per call, a mileage rate, and a charge of incidentals (e.g., linens, bandages, oxygen, splints, resuscitator, etc.). The charges used in this analysis are \$45 per call, \$10 for incidentals, and \$2 per mile between demand point and hospital. No distinction is made between patient transfers and emergency calls. It is assumed that the total charge is collected from 80% of the calls, since there is evidence that full payment in all cases is a rarity (California Dep. Transportation, p. 132).

The economic feasibility of the fifteen facilities, shown in table 2, varies directly with the number of calls serviced by the facility. Only in the first facility, serving a population of 68,511, does average revenue exceed average cost. Deficits are substantial for low density sites.

The average cost per resident of the entire study area is \$4.63 per year for providing this service. If the revenue generated by the system is considered, the average cost per resident would be \$3.06 to provide a break-even system. Whereas the first-listed region more than breaks even, costs exceed revenues for the other fourteen locations, and the charges are prohibitive for the low density areas.

One alternative is to consider a volunteer system similar to rural fire departments. This method would eliminate labor costs (i.e., no full-time drivers or attendants and clerical staff); the rent, phone, and utilities are assumed one-half of the fully staffed facility; but insurance and depreciation are equal for both systems. Annual fixed costs for the volunteer system are \$6,500 as compared with \$70,000. The revenue for the volunteer system is reduced to \$20 per call plus \$2 per mile from the demand point to the nearest hospital, with charges 80% collectible. This method was evaluated for facilities showing less than 400

Table 2. Financial Analysis of Facilities Entering Optimal Program with Forty-Minute Response Time, Resident Population Only

Facility Site	Fully Staffed Facility (24 Hours per Day)					Volunteer Facility for < 400 Calls per Year	
				Cost per Resident		Cost per Resident

[a] Indicates cities that currently either have commercial or volunteer ambulance services.
[b] Facilities with greater than 400 calls per year where costs equal those shown in columns to the left.

calls per year or slightly more than one call per day.

The financial feasibility of the combined fully staffed facility (greater than 400 calls) and a volunteer system (less than 400 calls) is improved considerably as shown in the last two columns of table 2. If the cost of the system is shared equally by residents of the area, it drops from $4.63 to $2.01 per resident; if revenues are added, the deficit drops from $3.06 to $0.54 per resident. The question still remains as to whether residents of a break-even area would be willing to be assessed to cover deficit, volunteer-force areas.

Funding Alternatives

A feature of emergency health service is that its availability is important not only to residents but to transients as well. Even for the resident population, there is no assurance that an accident or acute illness will occur within the service area of an established EMS facility. The questions then center on deciding the response time standard, the quality of this service (full facility versus volunteer service), and the allocation of costs of these services.

If health planners or policy makers conclude that the current spatial pattern of EMS facilities is inadequate, what will be the fiscal outcome? The question can be analyzed by comparing the "present system" with the "optimal system" presented in table 2. An analysis of the financial feasibility of the "present system" EMS locations (for the forty-minute response time standard), using the cost and revenue structures given above, indicates that only one of twelve locations can break even with a twenty-four-hour fully staffed facility. The difference between revenue and cost per resident with present location facilities ranges from −$0.28 to $43.47, compared with −$0.23 to $201.79 for fully staffed optimally located facilities as shown in table 2. Clearly, quality specification in our model is above that found in current facilities. But an interesting question is: If health planning agencies specify a given response standard, who is to pay the cost? The findings indicate that private purveyors would find it unprofitable except in heavily populated areas or where ambulance services are a secondary activity. The latter is the case in this study area, but detailed analysis of these businesses is beyond the scope of this study.

Funding alternatives to maintain a high quality EMS system include:[10] (*a*) increases in charges by private purveyors, but this alternative appears infeasible for most areas;[11] (*b*) direct or indirect subsidies to operators; (*c*) public operation of services; and (*d*) grants by state or federal agencies.

Subsidy schemes can originate at the local, regional, state, or federal level. An example of an indirect subsidy is where a regional regulatory board creates a spatial monopoly for an EMS purveyor—a common arrangement for some ambulance services. The model used in this study essentially traces out such spatial boundaries, and if only one purveyor operates in each area, it has a spatial monopoly. Thus, franchising, exclusive contracts, and zoning allow EMS purveyors to increase the number of calls and achieve lower average costs.

Direct subsidies at the local level might include use of local tax revenues to reimburse purveyors for noncollectible charges, dry runs, or indigent patients not covered by Medicare or Medicaid. The level of annual subsidy for the sparsely used facility (see table 2) is over $69,000 per year. Some of these service areas cross county lines, however, and regional funding might result in more efficient delivery of services.

Regional operation of EMS facilities might be organized similar to a cooperative. Facilities could be privately or publicly owned. Public finance literature contains a wealth of examples where goods and services are provided by the public rather than the private sector (see Musgrave and Musgrave). Funding might be provided by a multicounty tax district to subsidize losses for the entire system.

Subsidies using state or federal tax funds differ in an important respect in that residents and nonresidents would provide source of funding. Due to the possible use of facilities by nonresidents, this approach has some merit. Here, the user or immediate potential user

[10] The use of prepaid EMS is another possibility. There are two problems here: (*a*) the costs would be prohibitive unless funding is on a regional basis, and low density areas would be subsidized by high density areas; and (*b*) since EMS is rarely denied anyone in need of emergency care, a "free rider" problem develops. One reviewer noted that demand may be affected with this type of financial mechanism. The simultaneous nature of demand, location, and type of payment is acknowledged, but the investigation of this system was beyond the scope of this study. This question is also commonly debated with regard to the issue of national health insurance.

[11] Although the model assumes perfectly inelastic demand, this assumption is realistic only over some price range. At some price, the demand for EMS would apparently have a positive slope.

does not pay the full cost of the service. State funding could be provided from the sales tax, which is returned to cities and counties from which it is collected. Again, the sparsely populated counties would probably have strong demands on any such limited funds that would be available from this source.

Grants are another source of funding. Federal and state agencies as well as some private foundations have been willing to provide EMS equipment or funds to purchase ambulances and communication equipment. Regional Medical Programs, Robert Wood Johnson Foundation, Cranston Funds (PL 93-154), and the California Office of Traffic Safety are examples of such funding sources. Grants of equipment should be considered annual grants over the depreciated life of the equipment. At the end of that time a similar subsidy must be obtained or a depreciation reserve accumulated in order to continue the service.

Summary and Conclusions

The current debates on provision of medical services in general and emergency services in rural areas in particular appear to suffer from a lack of economic analysis. Using the EMS goals and standards set out by the state of California to serve rural and semirural areas, this study provides a framework under which policy analysis can proceed more rationally. EMS facilities that comply with response time standards, similar to those of urban areas, were prohibitively costly in the rural parts of the study area. Increasing the response time standards reduced the regional cost of the EMS systems and allowed some of the individual EMS facilities to become economically viable, since additional people could be served by each facility. The trade-off between cost and various response time standards was a key part of the analysis. A by-product of the regional cost estimate was the most efficient (least-cost) spatial pattern of EMS facilities for the study area.

There are important gaps in the analysis. The question of trade-offs in response time and system cost are but a first step. Medical input is needed to provide the loss function associated with delays in response to various types of accidents. We consider only ground ambulance service, whereas remote areas could also be served by helicopters. (See Plaas et al. for bibliography of studies on alternative transport systems.) The analysis does not consider multiple accidents and the need for back-up facilities in some areas, which is primarily a queuing problem.

This framework will be useful to regional medical planning groups. Of particular interest are the high costs involved in providing services to remote areas. The use of volunteer services would appear to be a necessary condition for persons selecting nonurban living environments. Sources for financing such services must be viewed in a broader context of local, state, and federal tax structures. Recommendations on funding of a particular service, such as EMS, would be presumptive without analysis of all demands on a rural economy. However, if the goal is to obtain efficiency in the delivery of services, major categories should be analyzed on a broad enough regional basis to allow consideration of reorganization of such services on an efficient basis. Particular attention should be paid to the relation between planning goals or standards and the associated costs. This study approach should be of use in analyzing delivery systems for several other services in rural areas.

Rent Extraction and the Survival of the Agricultural Production Cooperative

Andrew McGregor

During the last twenty years there has been a proliferation of production cooperatives in the agricultural sector of low income countries. This paper examines the prospects for this type of firm in light of their poor historical record. A theoretical model is presented that shows the extraction of scarcity rents is a necessary condition for survival. Several case studies examined are found to be empirically consistent with the model. It is shown that policies can be devised for the extraction of rents.

Key words: New Guinea, paradox of success, Peru, plywood cooperatives, production cooperatives, rent.

For this paper, a production cooperative is defined as a self-managed association for the purposes of production. The members must work in the enterprise and manage it according to democratic principles. This analysis excludes utopian communal societies operating outside the economic mainstream and also excludes enterprises like the Soviet Sovkhozy and Kolkhoz.[1] In addition, this production cooperative differs fundamentally from the conventional agricultural marketing cooperative. (A marketing cooperative may be involved in production in the sense that it processes the product of its members. Yet, the members perform their producer role outside the cooperative.)

Today production cooperatives are most significant in the agricultural sector of low-income countries. It is here that the findings of this paper are of greatest practical relevance. Since World War II, the circumstances of agricultural production cooperatives have been numerous and varied. Governments have sometimes promoted them as replacements for existing institutions that have failed to meet their development objectives. For example, as part of the 1969 Peruvian agrarian reform, the large sugar haciendas were converted to cooperatives.[2] A similar pattern was observed in Chile during the Allende era. In both Yugoslavia and Algeria, state farms have been reconstituted as cooperatives. Tanzania has adapted the production cooperative to the traditional village structure in the form of the Ujamaa village. In some instances production cooperatives have been promoted as a means of opening up new agricultural land. The Israel kibbutzim, in part, fit this category. A number of settlement schemes in the South Pacific have involved production cooperatives. On occasions agricultural producer cooperatives have evolved spontaneously with little or no government involvement. A number of cooperative plantations in New Guinea are examples.

The production cooperative is not a new phenomenon. Industrial production cooperatives were numerous in nineteenth century Britain and France. Significantly, the attrition rate for these cooperatives was such that they had all but disappeared by the First World War.[3] The majority of the nineteenth century cooperatives failed for financial reasons. The

Andrew McGregor is a lecturer in economics at Wollongong University, Australia, and is currently completing his Ph.D. at Cornell University.

The author is particularly indebted to Jaroslav Vanek who provided the inspiration for this paper. He would also like to thank Peter T. Knight and two anonymous reviewers for their constructive comments.

[1] The Sovkhozy are state-operated farms employing wage-earning employees. The Kolkhoz are peasant collectives, yet they cannot be regarded as self-managed associations. The chairman of the Kolkhoz is a government appointee. Further, most major production decisions come from outside the firm (Nove, p. 47).

[2] Initially, the sugar haciendas together with the coastal agroindustrial complexes were converted to cooperatives in name only. Management committees were dominated by government representatives. Further, the minority worker representative was elected in an undemocratic fashion. In April 1972 the system was radically changed. Management was placed exclusively in the hands of democratically elected workers (Gouverneur, pp. 199–202; Horton, pp. 60–64; Vanek 1973).

[3] An indication of the attrition rate is that of the 253 production cooperatives created in Britain between 1862 and 1880 only 28 still existed as cooperatives in 1892 (Jones, p. 115).

contributing factors included inadequate legal status and protection, poor management, and insufficient capital.[4] Further, British cooperatives in the latter part of the nineteenth century were adversely affected by trade union hostility. Yet, not all producer cooperatives were financial failures.[5] Paradoxically, the survival rate for the financial successes was no better than for the financial failures.

It is this apparent "paradox of success" that causes the most concern when appraising the potential of production cooperatives. It suggests that in the long run a production cooperative will not survive irrespective of legal status, quality of management, and social environment. An explanation of this paradox is presented. I will argue that a production cooperative can survive, but only if scarcity rents are paid to nonlabor resources.

The Nonpayment of Scarcity Rents by Production Cooperatives

Historically, production cooperatives have not paid scarcity rents to capital because of internal financing. Establishment capital was obtained, through both necessity and desire, from the collective contributions of members.[6] They were subsequently financed through retained earnings. The foregoing of the capital market precluded the necessity to make any payment to capital. (Unlike many consumer and marketing associations, production cooperatives have rarely made any payments to internally raised capital.[7])

Substantial internal financing is a feature of agricultural firms even in the most highly industrialized economy. An agricultural production cooperative without sizable government assistance is unlikely to be an exception. Unfortunately, when assistance has been forthcoming, it has been in the form of land grants, accentuating the problem of rent extraction. (The cooperative receives free, or at minimal cost, a resource that makes a major contribution to its members' income.) The Peruvian sugar cooperatives provide an excellent example of this occurrence (Horton, pp. 57–66). A plantation examined in the paper is another such case.

Theoretical Implications of Not Paying Scarcity Rents

The following theoretical discussion draws on the work of Domar, Ward, and in particular Vanek (1975). The model is similar to those developed for marketing cooperatives in the sense the firm's objective is to maximize the surplus per unit of patronage (Helmberger and Hoos, Helmberger, Youde and Helmberger). Yet, the nature of patronage for a production cooperative (labor input) makes the model fundamentally different.

Consider this simple model of an agricultural production cooperative. As a typical agricultural firm, it is a price taker operating under constant returns to scale. The members supply all the cooperative's labor. Their objective is to maximize income per worker. Formally, this can be stated as

$$y = (P_x X - P_z Z - P_v V)/L, \tag{1}$$

where y is the income per member, P_x is the product price, X is the output, P_z is the rents paid to capital and land, Z is the quantity of capital and land, P_v is the price of nonlabor variable inputs, V is the quantity of nonlabor variable inputs, and L is the number of workers. Assume that this cooperative is exclu-

[4] In Britain before 1864 it was illegal for cooperatives to sell to anyone but their own members. Each member was defined as a partner and as such could "pledge the cooperative's goods and credit and take its money without any effective remedy" (Jones, p. 121). Without the protection of limited liability, it was difficult to attract new members. Regardless of the size of his shareholding, each member was under unlimited liability to pay creditors if the association defaulted.

[5] In nineteenth century Britain, Jones reports very successful cooperatives in the textile and shoemaking industry (pp. 260–61, 402–16). The same can be said for the precision instrument cooperatives in France (Digby, p. 69; Willson, p. 26). In the United States, plywood cooperatives established just after the First World War have been among the most successful firms in the industry.

[6] The cooperative was often the product of a strike or a lockout, leaving banks and other lending institutions unfavorably disposed to them. The desire for internal financing resulted from the assumption that asset ownership was a necessary condition for enterprise control.

[7] Most marketing and consumer cooperatives trace their origins to the Rochdale Pioneers. The Pioneers and their adherents argued that while capital should not be the claimant of any surplus it should be paid the market rate of interest. Rochdale cooperatives, in varying degrees, have satisfied this maxim by paying dividends in accordance with members' individual capital contributions. Historically, production cooperatives have not been a part of the Rochdale movement and have generally not adopted this procedure. The decision not to make payments to internally raised capital has often had an ideological basis. In this respect the influence of the nineteenth century French intellectual Phillipe Buchez was most significant. (Buchez is generally regarded as the "father" of self-managed production associations.) A fundamental tenet of the Buchezian philosophy is that the capital of a cooperative should be "social, inalienable, and indivisible" and that members be paid only in accordance with their work (Reibel, p. 40). In some more recent situations, Marxist ideology has tended to preclude interest payments to capital (the Yugoslav firm provides an example).

sively internally financed and that it received its land as a government grant. As a consequence, it pays no capital or land rents, and equation (1) is reduced to

$$(2) \qquad y = (P_x X - P_v V)/L.$$

Given equation (2), y always increases with the average product of labor (X/L). Thus, with X/L inversely related to L, for any given quantity of land and capital, it always pays the cooperative to reduce its membership. Consequently, it never replaces a member who retires or dies unless the new member contributes sufficient capital to increase X/L. This incentive to reduce membership is the result of capital and land rents not being separated from labor income in the determination of y; it pays to share any given level of rents among as few workers as possible.

If L decreases, so does, *ceteris paribus*, the marginal productivity of capital and land; the capital-labor and land-labor ratios increase. The effect of this is an incentive to disinvest; the returns from capital and land are now less than what was previously desirable. An agricultural firm can disinvest in a number of ways. Soil conservation practices can be reduced, maintenance of irrigation canals can be neglected, the rate of replacement of tree crops can be reduced, etc. Any restoration of the desired rate of return is purely transitory, for the incentive to reduce working membership always remains.

Coupled with a tendency to disinvest a propensity to underinvest may exist. (Underinvestment occurs when the rate of return exceeds the decision maker's rate of time preference.) Conventional investment theory maintains that a rational individual invests until the rates of return (A) and time preference (R) are equated. Implicit in this theory is the expectation that the invested principal is recouped at the end of the investment period.[8] For production cooperatives retained earnings tend to be regarded as the collective property of the membership, an individual benefiting from a collective investment entirely through increased y. Thus, individuals do not have the expectation of recouping any of the collectively invested principal.[9] Hence, an individual requires A to be higher than R to make an investment worthwhile. Formally, he is willing to invest if

$$(3) \qquad A \geq R + E \text{ for } E \geq 0.$$

The factor E is compensation for nonrecouped principal. It is a variable that increases at an increasing rate as the member approaches retirement. For a young worker the dimensions of E are trivial, but for a worker near retirement the rates of return have to be immense to justify an investment.[10]

If the age structure of the cooperative is stable, the propensity of the firm to underinvest remains constant. Yet a stable age structure is highly unlikely. If, as hypothesized, members who leave the cooperative are not replaced, the working collective gets "older" through time. The result is an increasing tendency of the cooperative to underinvest.

In the realistic event that the cooperative has a pension scheme for its members, the dimensions of E are modified. The most effective scheme in this respect is one that fixes the pension rate in a given year to the prevailing y. (A member has a financial interest in the post-

[8] If the invested principal is recouped, the present value of an invested dollar is given by

$$V = A \sum_{i=1}^{T} (1 + R)^{-i} + (1 + R)^{-T},$$

where V is the present value of the returns from the invested dollar, A is the annual returns from the invested dollar, R is the rate of time preference, i is the ith time period of the investment, and T is the total investment period. An extra dollar is invested until $V = 1$; at that point $A = R$. Consider the following empirical vertification: if $R = 6\%$, and $T = 2$, then when

$$A \sum_{i=1}^{2} (1.06)^{-i} + (1.06)^{-2} = 1,$$

$A = 0.1100/1.8334 = 0.06$.

[9] Marketing cooperatives sometimes use a revolving fund to return invested principal to individual members. (This involves issuing stock to members when earnings are retained and redeeming this stock after a fixed time period. Kohls [p. 236] reports that 61% of U.S. marketing cooperatives use this technique.) I know no case of a production cooperative using a similar technique. For some production cooperatives, the return of collectively contributed capital to individual members would be ideologically objectionable. (A basic Buchezian principle is that capital must be the permanent "social" property of the association.)

[10] If the invested principal is not recouped, the present value of a dollar invested is given by

$$V' = A \sum_{i=1}^{T} (1 + R)^{-i}.$$

Consider a young member who expects to work in the cooperative for another thirty years (assume $R = 6\%$). He would be willing to invest a dollar if

$$A \sum_{i=1}^{30} (1.06)^{-i} \geq 1;$$

i.e., $A \geq 7.2\%$. This represents an E factor of 1.2%. Take the same member two years before retirement. He would now be willing to invest a dollar if

$$A \sum_{i=1}^{2} (1.06)^{-i} \geq 1;$$

i.e., $A \geq 54.5\%$. The E factor has increased to a huge 48.5%.

retirement returns from an investment.) Yet, even if pensions are a high percentage of y, the magnitude of E is still likely to be higher for a member approaching retirement.[11]

Collective investment coupled with an "aging" membership provides a strong financial incentive to sell the cooperative within a working generation. After a period of some forty years, most, if not all, members will be close to retirement. Over this period they have collectively built up considerable equity in the cooperative. Thus, near retirement all members have a strong vested interest in selling the firm and distributing the receipts amongst themselves.

An initial assumption of the model is that the cooperative only employs member workers. This assumption, while consistent with cooperative ideology, is inconsistent with members' economic self-interest. It always pays to employ nonmembers if their fixed wage is less than the income per head (hired labor's contribution to total production always exceeds the cooperative's wages bill). This is illustrated in figure 1. (For simplicity, it is assumed that labor is the only variable input.) Suppose that initially the members supply om labor and no outside labor is employed, then income per head (y) is mf/om—the average product of labor. Suppose also that outside labor is hired at a wage given by the slope of line P_L. Income per head is maximized by hiring mb labor; at b the marginal product of labor (X_L) is equated to its price. The additional labor adds cd to revenue product at a cost in wages of only de; y has been increased by ec/om.

The incentive to reduce membership is independent of the employment of nonmembers. The cooperative depicted in figure 1 would reach an equilibrium of one member and $ob - 1$ employees. Clearly, the closer the firm is to this equilibrium, the less it resembles a cooperative.

It is the forces pushing the cooperative toward equilibrium, and not the equilibrium itself, that are important. In reality, an equilibrium of one working member is unlikely to be ever reached. The cooperative may be sold, if law permits, well before this point. Alternatively, underinvestment may lead to financial failure and liquidation. In other circumstances, equilibrium membership may be somewhat greater than one. The cooperative may pay a small portion of the scarcity rent of capital and land. (Land may not be a government outright grant.) This, as will later be shown, eventually halts the incentive to reduce membership. Increasing returns to labor can exist at low levels of labor input relative to land and capital. Under such circumstances, if the cooperative does not employ nonmembers, a point is eventually reached when any further decline in membership decreases X/L and thus lowers y.[12]

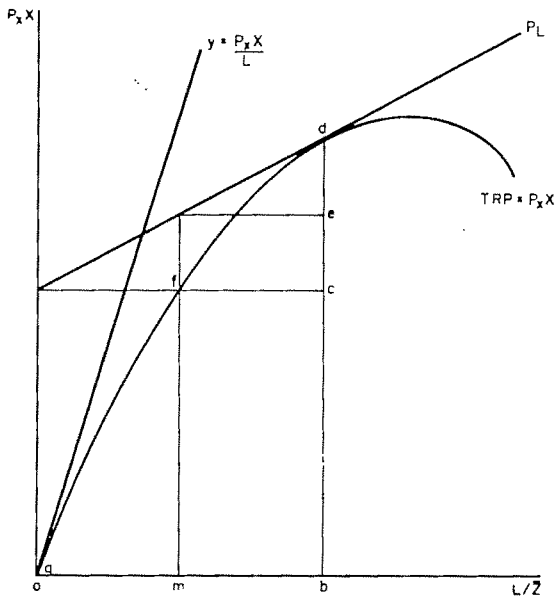

Figure 1. Short-run equilibrium of a cooperative

Recapitulating, the model hypothesizes a number of self-extinction forces that have worked aginst the long-run survival of production cooperatives. There is a desire to reduce

[11] Consider again a member two years before retirement. A particularly generous retirement scheme sets pensions in any year at 75% of y; the pension can be transferred to a surviving spouse. Assume the member expects himself or his spouse to live another twenty years after retirement. He would thus be willing to invest a dollar if

$$A\sum_{i=1}^{1}(1.06)^{-i} + 0.75\sum_{i=2}^{21}(1.06)^{-i} \geq 1;$$

i.e., $A \geq 10.5$. This represents an E factor of 4.5%.

[12] In a situation where a marketing or consumer cooperative failed to pay capital rents, members would receive this income as part of their patronage income. This would provide an incentive to reduce membership. However, unlike a production cooperative where labor input represents patronage, increasing returns are likely to exist over a considerable range of patronage (these increasing returns relate in particular to marketing economies and countervailing power). Such gains from increasing membership more than offset the loss associated with a decreased share of capital rents. As Youde and Helmberger point out, a marketing cooperative with considerable market power will eventually have an interest in restricting membership (an inverse relationship exists between patronage and product price).

membership, which in turn leads to an incentive to disinvest. The long-run financial viability of the firm is jeopardized by an increasing tendency to underinvest coupled with an increasing desire on the part of members to extract their equity. Finally, financial incentives exist for members to abandon cooperative ideals and hire wage-earning employees.

The Empirical Consistency of the Model: A Consideration of Some Case Studies

Two sets of case studies are examined in detail: a group of plywood cooperatives in the United States and two plantations in New Guinea.[13] An adequate time series of data are the main criteria for selecting the cases. Cases like the Israeli kibbutz are excluded on the grounds that noneconomic factors may obscure the hypothesized economic forces. As this model is concerned with the survival of financial successes, financial viability, at least initially, is a necessary requirement.

The U.S. Plywood Cooperatives

Data for these case studies were obtained from Bellas, Berman, and Worden.

Since 1921, there have been thirty-two plywood cooperatives in the Pacific Northwest region. They have constituted a significant but diminishing part of the industry. Despite a predominance of old, sometimes obsolete plants, the productivity of the cooperatives until the mid-1960s was significantly above the industry average.[14]

Membership of the cooperatives was obtained through share purchase. The number of shares sold was limited by the available jobs. Income was fixed to labor input. The benefits of being a shareholder accrued from working in the cooperative; rarely were dividends paid to shareholdings. Significantly, the majority of cooperatives reserved the right to purchase the shares of any member leaving the cooperative. Such purchases were at a price determined by the remaining members.

The cooperatives were predominantly self-financed, particularly those established before the Second World War. The Olympia Plywood Corporation, the largest of the cooperatives, was typical. After three years of operation, it had capital stock of $350,000 of which only $25,000 came from outside sources. Most of the cooperatives studied had bylaws in their constitution protecting the jobs of existing members. This supports the contention that any reduction in the working membership would be gradual.

Olympia clearly exhibited declining working membership. It was established in 1921 by 125 working members. In the subsequent successive years, the membership was 118, 108, 92, and 92. At the time of its sale in 1952, the number had dwindled to 45. During this period the firm expanded rapidly, so much so that it was purchased for stock valued at $15 million. During this period the cost of joining the cooperative continually increased.[15] Within very few years the price of the occasional Olympia share placed on the open market was prohibitive to younger and less well-off workers. Eventually, their price became prohibitive to all plywood workers.

The same sort of phenomenon was observed for the three other prewar cooperatives. For example, the Peninsula Plywood Company, established in 1941 by 280 worker shareholders, had only 240 working shareholders in 1958. During this period the value of the firm's capital assets had quadrupled.

In contrast, the cooperatives formed after the war experienced relatively little decline in working membership. This phenomenon is not contradictory to the explanation of the "paradox of success." These cooperatives were far less financially viable than their prewar counterparts. A depressed plywood market precluded the previous rapid rates of expansion. Hence, capital income accruing to members was far less, reducing the incentive to decrease working membership. In fact, some of these cooperatives were so chronically short of capital that they had to increase membership to raise sufficient capital for short-term survival. Further, a change in cooperative tax law in 1963 acted as an added disincentive to reduce membership. Following a court challenge, income distributed to cooperative members in accordance with

[13] I have examined in detail elsewhere a number of other case studies. These include the original Rochdale cotton mill, a nineteenth century British shoe cooperative, a twentieth century British chemical manufacturing cooperative, and the Yugoslav firm (McGregor 1974, pp. 27–30, 55–65, 86–99, 124–29). The findings were consistent with the cases presented here and thus for brevity have been excluded.

[14] A large number of cooperatives were established by employees of unprofitable conventional mills. They purchased mills that typically had run down and obsolete plant and equipment.

[15] Two years after Olympia was established, shares with a par value of $1,000 had a market value of $2,500. They eventually realized $120,000 when the cooperative was sold.

hours worked became tax deductible. For a firm to be classified as a cooperative for taxation purposes, it was necessary to maintain a high percentage of member workers.

Turning now to the employment of nonmember workers, the cooperatives established before the war displayed an increasing tendency to employ nonmembers. Olympia provides the most striking example. In 1922 out of a total work force of 218, 100 were not shareholders. By 1952 the firm had 45 working members and approximately 1,000 employees. Consistent with this model, the employees received considerably less remuneration than the members. (In 1922 employees received between $3.90 and $4.40 per day compared with $6.00 for members. By 1952 nonmembers received a daily wage of $15.60, approximately half the remuneration of members.) The postwar cooperatives also made increasing use of nonmembers. In 1956 six cooperatives employed only members, whereas by 1964 all cooperatives employed nonmembers. The replacement of member workers with nonmembers would render the hypothesized disinvestment force inoperative.

With regard to underinvestment, direct data are limited and difficult to evaluate. Nevertheless, some evidence of an increasing propensity to underinvest does exist. Over time there has been a steady decline in the productivity superiority of the cooperatives. (In the early 1950s, their productivity was, on the average, some 30% above that of conventional firms. By the late 1960s, the differential had all but disappeared.) Bellas attributes this to the much higher investment in new equipment by the conventional firms. Illustrative of this is that no cooperative has invested in a new plant since 1955. In contrast for the decade 1955–65, forty-one conventional firms invested in a new plant.

Evidence of an increasing desire on the part of members to extract their equity from successful cooperatives exists. Three financially successful cooperatives were sold within a working generation. Table 1 indicates the extent of the pecuniary benefits accruing to members from these sales.

Table 1. Financially Viable Plywood Cooperatives Sold

Cooperative Name	Year Formed	Year Sold	No. of Shareholders at Time of Sale	Sale Price ($1,000)
Olympia Plywood Corporation	1921	1954	65	15,000
Mutual Plywood Corporation	1950	1958	205	7,500
Anacortes Plywood Company	1930	1968	NA[a]	5,700

Note: To date four other cooperatives have been sold. These were financial failures that were sold very early in their life.
[a] The original working membership was 250.

The New Guinea Copra Plantations

Despite an expressed government policy to promote peasant proprietorship, a number of production cooperatives have evolved spontaneously. Eight of these cases have been documented since the war (Crocombe 1964, 1965, 1971; Crocombe and Hogbin; McGregor 1971). The author has first-hand knowledge of the two cases examined here.[16]

Both are located in the Manus region. One plantation, known as M'buke, comprises thirteen islands totaling 140 hectares. The other, known as Langandrowa, is on a single 104-hectare island.

The M'buke islands were planted by a German just prior to the First World War. The plantation was subsequently expropriated by the Australian Government in accordance with the Treaty of Versailles and sold to an Australian company. The M'buke people, the traditional claimants of the land, purchased the plantation in 1961. The M'bukes have operated the plantation as a cooperative, ignoring completely customary land rights.

The Langandrowa plantation was established at the turn of the century by a Japanese planter. It was expropriated as enemy property after the Second World War. The Mouk people, who now operate the plantation, obtained it as part of a government resettlement in 1965. Individuals were given leases to sixteen individual blocks. The government's intention was to have sixteen peasant holdings. This was not realized; forty-five Mouk families settled in a village and operated the plantation as one cooperative unit.

The M'buke plantation is owned and operated by a formal cooperative society (the

[16] The analysis is based on field work carried out during 1968–69. For a detailed analysis of the two plantations, see McGregor (1971, 1974). I also draw heavily on a previous study of the M'buke cooperative by Crocombe (1965).

M'buke Native Society Limited) and as such its activities are supervised by the Registrar of Cooperatives.[17] As a formal society, the M'buke cooperative was able to secure a $9,000 government loan to purchase the plantation. In contrast, Langandrowa is not a formal cooperative society.

In terms of productivity both cooperatives have performed particularly well. Despite the age of its trees, production per acre on Langandrowa has been some 30% above the national average for commercial plantations. Productivity increased ninefold under cooperative management. The productivity of the agronomically inferior M'buke plantation increased by 5% under cooperative management.

The M'buke cooperative initially paid substantial scarcity rents. By imposing a $28 per ton cess on sales, the government loan was repaid in three and a half years, a year and a half early. The cess was abandoned when the loan was finalized, and no further rents were extracted by the firm. (No rents were ever paid to the seven M'buke clans who contributed $4,000 to purchase the plantation.[18] Further, at the time of the field study no dividends had been paid to the shareholders.[19]) The Langandrowa cooperative has not extracted rents from the outset. The plantation was obtained for a nominal payment of $2 per annum for each of sixteen leases. Retained earnings has been the sole means of financing.

In October 1963, Crocombe reported the M'buke cooperative's working membership to be 107. By January 1969 it had declined to 91. During this period production was maintained and income per head had more than doubled. (It is significant that no villager under the age of twenty-five was a working member of the cooperative.) The M'buke case appears to be a particularly strong test of the declining working membership force. Here is a situation where cooperative members also belong to a cohesive village group with strong kinship ties. Yet, fellow villagers appear to have been denied working membership of the cooperative.

The Langandrowa cooperative had been in operation a relatively short period at the time of 1969 field work. Thus, any attrition in the existing membership could not be substantial. Nevertheless, a piece of evidence did exist that suggested that the force leading to declining working membership was becoming operative. In February 1969, a group of forty-six people from the previous Mouk village requested to join the cooperative. Despite the fact that these people had no arable land of their own, and their very strong kinship ties, the request was refused.

The employment of nonmembers on the irksome task of plantation clearing has been an increasing phenomenon on M'buke. In 1963 only 20% of clearing was done by nonmembers; by 1969 it had risen to 50%. As predicted, the remuneration of nonmembers was less than for members (64¢ per day compared with 88¢ per day for members.)

During 1968, 2% of Langandrowa's copra was gathered by outsiders. (Nonmembers received 1.6¢ per pound gathered, compared with 2.21¢ per pound for members.) Prior to this no outsiders were employed.

Some evidence of disinvestment was revealed on the M'buke plantation. M'buke's palms are old, yet no systematic replanting was observed. Even dead palms appeared not to be replaced. By 1969 copra driers, constructed by the cooperative in 1963, were in derelict condition.

Evidence of underinvestment on the M'buke plantation itself was not found in 1969. Investment opportunities were quite limited; the plantation was fully planted, and its physical nature precluded any mechanization. Nevertheless, strong *prima facie* evidence of the underinvestment force did exist. In 1968 the government offered the M'buke cooperative a ninety-nine-year lease on some nearby copra islands. For an initial investment of $700 and subsequent annual payments of $188, annual net revenue could have been increased by some $2,000 (assuming 1968 prices). The islands were not fully planted; thus, long-run revenue could have been increased by substantially more. The increased revenue could have been achieved without any apparent strain on labor resources. Yet, the cooperative members voted against foregoing current income to secure the islands.

[17] During the 1950s and 1960s the Australian administration vigorously promoted formal Rochdale marketing and consumer cooperatives at the village level. As a part of this program, the M'buke society was established in 1955 to market village copra and trochus shell and provide a retail store.

[18] The cooperative did not issue any shares for these collectively contributed funds. Thus, there was no potential for extracting rents through the payment of dividends.

[19] At the end of 1963 the cooperative's share capital was approximately $14,000 (share capital per member ranged from $10 to $165). The Registrar of Cooperatives vetoed the payment of any dividends for the first six years of operation on the grounds that the cooperative was severely undercapitalized.

There was no evidence of underinvestment for the newly formed Langandrowa cooperative. During its first few years of operation, substantial investments were made in transportation and processing facilities. The returns from these investments are likely to have been high due to the physical nature of the plantation.

Some Policies to Extract Scarcity Rents

Assume a cooperative obtained all its capital and land with funds secured from a perfectly competitive capital market. Under such circumstances, the firm's repayments reflect the scarcity value of these resources, and all the hypothesized self-extinction forces become inoperative. Let us briefly consider this proposition.

With all the cooperative's funds coming from a competitive capital market, the objective function becomes

$$(4) \qquad y = (P_x X - RZ - P_v V)/L,$$

where R is the competitive interest rate (i.e., society's rate of time preference).

The incentive to reduce membership is checked by the cooperative's debt obligation to the capital market. In figure 2, with $\bar{Z}$ capital and labor resources, y is maximized with

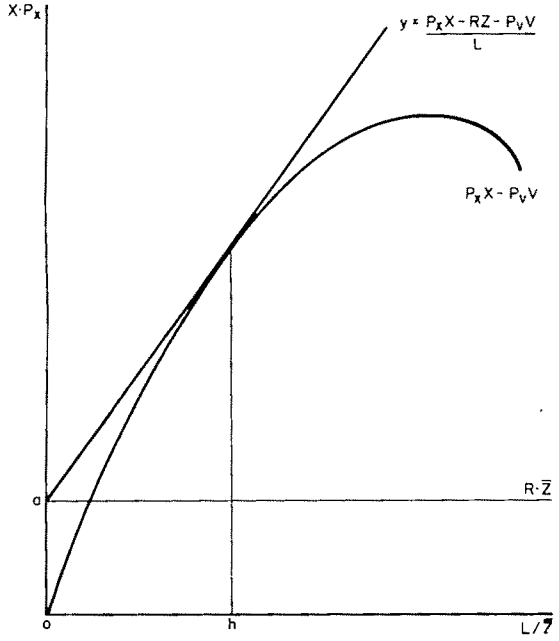

Figure 2. Short-run equilibrium of a cooperative (with scarcity rents)

oh members. (At equilibrium $MP_L = y$.) With all investment funds coming from the capital market and not from collective contributions, the underinvestment force is eliminated. The cooperative continues to borrow investment funds until their rate of return equals R. Furthermore, individual members do not continually build up equity in the cooperative; hence, the increasing desire to sell is removed. The financing of cooperatives through a perfectly competitive capital market reduces, and eventually eliminates, the incentive to employ nonmembers. The payment of a fixed debt obligation reduces y and thus the economic incentive to "exploit." Under perfectly competitive conditions, any remaining positive between y and P_L is eliminated by the establishment of new cooperatives.

A perfectly competitive capital market is of course an ideal that is unlikely to be approached in a realistic economy. For a low-income country, it would be unrealistic to assume the existence of a capital market that could facilitate anything near 100% external funding, particularly for an agricultural firm. Thus, the above discussion is only relevant in so much that it suggests a basic principle that must be adhered to in any policy proposal. This principle is that scarcity rents must be paid to nonlabor resources.

Rent Extraction by Government Legislation

This proposal draws heavily on Vanek, in cooperation with McGregor and Richards. It is worthy of note that elements of the Peruvian Social Property legislation incorporated some of the underlying principles discussed here (Davis, Gouverneur, Vanek 1973).

A government intent on establishing production cooperatives could extract scarcity rents by legislation. This could be achieved in the following manner. Land could be made available at a base scarcity rent. In addition to this base rent, the cooperative would be required to withdraw an amount equal to a fixed percentage of its capital stock annually, the rate reflecting capital's scarcity value.[20] Thus, if r^* reflects the combined scarcity of capital and land, and Z is the stock of capital and land, then r^*Z is withdrawn annually. Out of r^*Z the cooperative must meet any external debt obligation. The cooperative has three options for the remainder. It could reinvest in the

[20] An investment that improved the quality of land would be classified as an addition to capital stock.

cooperative. (It should be remembered that if θ_t was reinvested in the current year, the cooperative must extract $r^*(Z_t + \theta_t)$ the following year.) Alternatively, any part of the remainder could be used to establish new independent cooperatives or placed in a government fund. (The government fund would be used to provide land and finance for new cooperatives.) Any part of r^*Z not reinvested generates no further income to members nor do they have any further rent payment obligation for it. Under these circumstances, reinvestment in the cooperative would only be rational if the rate of return (A) exceeded r^*.

Such legislation produces the following objective function for cooperatives:

$$(5) \qquad y = (P_x X - r^*Z - P_v V)/L.$$

If $r^* \doteq R$, then substantially the same solution as results from a perfectly competitive market follows.

The fixed debt obligation for a given stock of capital and land checks the desire to decrease working membership.

For the amount r^*Z, members no longer have the choice between consumption and collective investment. It is either reinvested in the cooperative or foregone. It is irrational to underinvest, for it will always pay individuals to reinvest r^*Z so long as $A > r^*$. A further potential advantage of the proposal is that it may facilitate the movement of funds into more productive uses. (Any retained unproductive funds now incur a financial cost r^*Z.) For example, plantation agriculture, hitherto stagnating because of inadequate marketing facilities and land shortages, may have funds moving into the opening up of new land and establishing processing and transport facilities.

The extraction of r^*Z reduces any positive discrepancy between y and P_L and thus weakens the incentive to employ nonmembers. This follows not only from an increase in the fixed debt obligation of cooperatives but also from a possible fall in product price through increased industry output.

In a real world policy context the proposal may have considerable merit. The rate of r^* would be manipulated to achieve employment and output objectives. An upward adjustment in r^* could be used as a means of increasing productivity and employment. This can be seen in figure 3. (It should be noted that any reduction investment resulting from increasing r^* will modify this effect.)

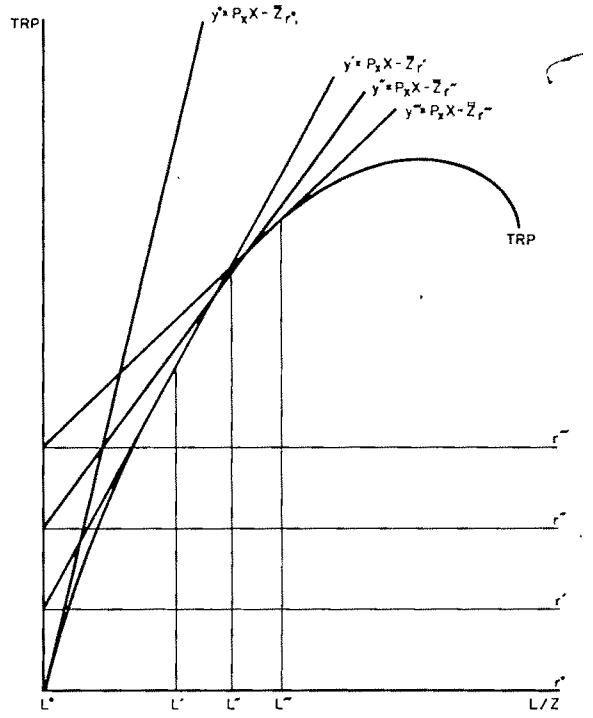

Figure 3. The effect of changes of rents on employment and income

Intrafirm Rent Extraction: Rochdale Cooperatives and Lessons from the Pioneers

Since the Second World War a number of governments have promoted formal Rochdale cooperatives as part of their rural development program. In keeping with the traditions of the Rochdale movement, this has invariably meant the promotion of marketing and consumer societies. Nevertheless, while production cooperatives were not seen as the goal, they have resulted in a number of instances (Crocombe 1971, p. 171). Usually, as with our M'buke case, these "Rochdalean" production cooperatives evolved from previously established marketing or consumer societies.

The system of financing that these "Rochdalean" production cooperatives have inherited potentially provides an intrafirm means of overcoming the hypothesized self-extinction forces. Like most marketing and consumer societies, they issue shares to individual members in accordance with their capital contributions, with bonus shares often being issued when any surplus is retained (all members having equal voting rights regardless of their shareholding). If dividends are paid that

approximately reflect capital's scarcity value, the incentive to continually reduce working membership is eliminated (assuming land has not been provided as a government grant and bonus shares are always issued when earnings are retained).[21] This follows because the residual income accruing to the members would represent the contribution of their labor alone. (The incentive to disinvest would be eliminated *pari passu*.) The underinvestment force would also be eliminated if individual members can redeem their shares on retirement. (With bonus shares being issued when earnings are retained, an individual's shareholding would reflect his contribution to the cooperative's capital stock.)

Notwithstanding the potential for intrafirm rent extraction, insufficient internal funds may be available to establish a viable enterprise. The purchase of land alone may be beyond the collective means of a group of rural workers or peasants. (The New Guinea case studies are examples of this.) With the relative fixity of land necessarily limiting the working membership, a temptation may exist to attract nonworking members as a means of raising capital. Such an action could prove disastrous for the cooperative. A valuable lesson in this respect can be learned from a brief examination of the important historical case of the Rochdale Pioneers.[22]

Initially, the Pioneers saw in production cooperatives a means of improving the lot of workers. To this end they established in 1854 a cooperative cotton mill. To begin with, most of the hundred or so shareholders worked in the mill. The few nonworking members were altruistic Pioneers; their capital was required to lease a room from an established mill. As shareholders the nonworkers were given full and equal voting rights. Despite an acute capital shortage, the cooperative fared better than most mills during the severe 1857–58 market slump. To quote the "Rochdale Observer":

> The disastrous years of 1857 and 1859 sorely tried this infant establishment; and, although during a period of fifteen weeks no sales were effected, or sales only to a trifling amount, yet the hands were never put on short hours, although other mills in town yielded in this respect to the pressure of the times (Jones, p. 260).

The subsequent 1859 price boom left the cooperative in a very favorable economic position. It began to attract members who had little or no involvement with the cooperative movement. These new members were not required to work in the mill, and few did. The cooperative actively encouraged nonworking members to finance a £34,000 mill. By the end of 1860, the "cooperative" had 1,400 shareholders of whom only 200 worked in the mill. All the management committees were made up exclusively of nonworkers. The previous policy of distributing the trading surplus among the working members was abolished. Instead, workers were now paid a fixed wage that was little above the going rate for the industry. A dejected Pioneer, Abraham Greenwood, described what had occurred:

> It was the success of the society that attracted to it persons who only cared for the eternal "divi." These people brought into the society their money very rapidly for shares, thus raising the number of shareholders from 200 or 300 to 1,400. It was the new shareholding element that swamped the original promoters of what was then called "Bounty to Labour" (Jones, p. 262).

While a production cooperative should never admit nonworker members, outside investors should not be discouraged. It could sell, the capital market permitting, bonds and debentures to outsiders. This stock would exercise no control but would facilitate rent extraction at the market rate of interest. (Payments to bond and debenture holders are made before any surplus is distributed among the members.)

Summary and Conclusions

Since the Second World War there has been a revival of interest in production cooperatives, particularly in the agricultural sectors of low-income countries. For an increasing number of third world policy makers, the production cooperative appears to offer a superior alternative to both the private and state corporations.

[21] In practice many Rochdale societies pay dividends well below the market rate of interest. The M'buke cooperative provides an extreme example. In the first six years it operated the plantation, no dividends were paid.

[22] Data for the following brief discussion are derived from Bonner, Jones, and Potter. This case represents an historic turning in the Rochdale movement. It led to the disillusionment of the Pioneers with production cooperatives, and they turned their energy entirely to consumer societies. The case so influenced the Fabian socialists that they actively campaigned against production cooperatives. (The Fabian socialists in Britain played a vital role in consolidating consumer cooperatives in the latter half of the nineteenth century.)

If history can be our only guide, we can only be pessimistic regarding the survival prospects for these firms. An historical review revealed that nineteenth century cooperatives seldom lasted more than a decade—paradoxically, the survival rate being no better for financial successes. It was shown that, if scarcity rents are not extracted from land and capital, a New Guinean cooperative copra plantation will meet the same fate as the Wolverhampton locksmith societies a century ago. In fact, the demise of the New Guineans may be faster due to the production relationships of plantation agriculture.

Yet, this paper should provide grounds for optimism, not gloom, for present-day cooperators. Policies can be readily devised to facilitate rent extraction. The principle of rent extraction seems equally amenable to government legislation as it is to intrafirm policy.

Inflation-Indexed Price Supports and Land Values

Duane G. Harris

A theoretical model is developed to examine and illustrate some relationships between cost-indexed support prices and land values. The model is developed in the context of a single-commodity, price-uncertain world in which policy makers are allowed to control the percentage of nonland operating costs and the percentage of land costs covered by the support price. The model demonstrates that the time path of land values can be quite sensitive to policy parameters. Attempts by policy makers to guarantee a "fair" rate of return on land may have substantial impact on future land values.

Key words: farm policy, land value, support price, target price.

Land prices have an impact on a wide range of participants in an economy. They have a direct impact on farmers' abilities to begin, operate, and expand their enterprises. Consumers worldwide are affected indirectly by land values because the cost of land services partly determines the supply of farm commodities. Taxing authorities are directly affected by land value changes because property values are used as the basis for property tax assessment.

In addition to such factors as farm income, farm enlargement, and expected capital gains, many studies have documented the influence of government farm programs on land values. For example, Reynolds and Timmons find, by using 1933–65 aggregate U.S. data, that payments made through government farm programs are indeed capitalized into farmland value. Boxley and Anderson summarize various studies that show positive values for tobacco allotments. Hedrick documents that benefits of the peanut program are capitalized into land values in North Carolina.

With the adoption of the Agriculture and Consumer Protection Act of 1973, however, the thrust of farm programs in the United States was changed. Programs to restrict supply were replaced with ones to promote production. Policies to stabilize commodity prices were replaced by a new policy of target prices. Although it is not clear that future farm programs will take the form of the 1973 Act, general interest in the inflation indexing of economic variables likely will cause some form of cost-indexed price supports to be considered seriously in the future.[1]

Unfortunately, because of limited experience with inflation indexing, it is not possible to empirically document or project the impact of cost-indexed support prices on land values. It is possible, however, to develop and illustrate some of the potential important relationships between support-price policies and land values. The purpose of this article is to present such conceptual relationships.[2]

In the next section, a theoretical model of land value determination is developed to incorporate support prices. Then, the model is illustrated for different assumptions about the implementation of support-price policy. Finally, a summary and some conclusions of the study are presented.

Duane G. Harris is an associate professor in the Department of Economics, Iowa State University.

Journal Paper No. 8660 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa, Project No. 2117. The author wishes to thank Roy D. Adams, Michael Boehlje, Roy Gardner, Wallace E. Huffman, John A. Miranowski, and Ronald Raikes for helpful discussions during the development of this paper. Appreciation is also extended to David L. Reinders for programming assistance. Finally, referee Jerry A. Sharples and an anonymous reviewer offered suggestions that significantly improved the manuscript.

[1] For example, escalator clauses in labor contracts, automatic inflation adjustments in retirement and pension plans, and inflation-indexed bonds all represent inflation-indexing mechanisms.

[2] The analysis is confined to an examination of the impact of cost-indexed support prices on land values. No evaluation is made of the impact of support-price policy on stability of commodity prices or on income support in the farm sector.

A Model of Support Prices and Land Values

General Framework

Assume a simplified world in which one commodity is produced from land in time period t. Also assume that the future level of per acre production Q_t is certain and constant. If the farmer sells the commodity at random unit price P_t and incurs the certain per acre cost of production (exclusive of land cost) C_t, then the farmer's per acre net return to land can be written as

$$R_t = P_t Q_t - C_t, \tag{1}$$

where price uncertainty constitutes the only source of risk and causes net return to be a random variable. The expected level of net return per acre is thus given by

$$E(R_t) = E(P_t)Q_t - C_t, \tag{2}$$

and the variability of return is given by

$$\sigma_{R_t}^2 = Q_t^2 \sigma_{P_t}^2. \tag{3}$$

Furthermore, by assuming that the expected probability distribution for future prices is constant so that the expected value and variability will be the same in all future time periods, the value of farmland V_t is given by the standard valuation formula

$$V_t = \frac{E(R_t)}{k}, \tag{4}$$

where k is the capitalization rate given by

$$k = a + b\sigma_{R_t}^2. \tag{5}$$

In equation (5), the coefficient a represents the risk free rate and b is the unit increase in k brought about by a change in risk as measured by $\sigma_{R_t}^2$. Any factor that causes expected return to increase increases land value. For a risk averter, any factor that causes variability (risk) to increase increases the capitalization rate and thus decreases land value.[3]

Support-Price Mechanism

Suppose that, as a matter of policy, a support price X_t is automatically implemented as a function of the per unit cost of production of the commodity. Specifically, let

$$X_t = \frac{\gamma_C C_t + \gamma_L L_t}{Q_t}, \tag{6}$$

where C_t/Q_t represents the operating cost, L_t/Q_t represents the land cost per unit of production, and γ_C and γ_L are policy decision parameters used to establish the proportion of operating and land charges that will be recaptured via the support price per unit of the commodity.

By assuming

$$C_t = \delta C_{t-1} \tag{7}$$

and

$$L_t = \lambda V_{t-1}, \tag{8}$$

equation (6) can be rewritten as

$$X_t = \frac{\gamma_C \delta C_{t-1} + \gamma_L \lambda V_{t-1}}{Q_t}. \tag{9}$$

Equation (7) defines current operating costs as proportional to last period operating costs, where δ represents the value $(1 + c)$ and c is the rate of growth (decline) in operating costs. Equation (8) establishes total land charges as a return on last period land value, where λ is the rate of return and is a policy decision parameter that is established as the allowable rate of return on farmland that can be considered as a land charge for support-price purposes.

Price Expectations and Land Values

To identify the expected returns and capitalization rate necessary for the determination of land value, it is necessary to postulate a farmers' subjective probability distribution for commodity prices. To keep the analysis simple, the distribution is assumed uniform, ranging from the support price X_t as the lower bound to U_t as the upper bound.

It is assumed that the support-price mechanism changes the subjective probability distribution. For example, a loan rate mechanism establishes a floor on the distribution of market prices and thus bounds the farmers' distribution of expected prices from below. A target price formula, although it does not alter the distribution of market prices, changes the farmers' distribution of expected prices because the formula provides for a transfer of income to make up any deficiency between market price and the target price. As used in

[3] Valuation formula (4) could be modified to accommodate net returns that grow at a constant rate g over time. In that case, $V_t = E(R_t)/r$, where $r = (k - g)$. In such a model, expected returns would grow over time, but the variability of returns would remain constant such that the capitalization rate would be constant over time.

this paper, the support-price mechanism is generalized to accommodate either a target price or loan rate program. (For a discussion of current loan rate and target price formulas, see Penn and Brown.)

Furthermore, once the support price is established by the policy authority, assume farmers expect that policy to prevail forever. If the policy authority changes the support price, farmers revise their expectations but again believe that the new support price will prevail forever. Thus, at any given time, farmers are basing the valuation of land on an expected distribution of returns that is constant over all future years.[4]

Also, if the support price is changed, the mean of the distribution is assumed to shift, but the variance remains unchanged. For example, if the support price is increased by x units, the upper bound of the distribution also increases by x units.[5]

The upper bound of the distribution U_t can be defined as the sum of the lower bound X_t and the range RG_t. From equation (9),

$$(10)\quad U_t = \frac{\gamma_C \delta C_{t-1} + \gamma_L \lambda V_{t-1}}{Q_t} + RG_t.$$

The first two moments of the uniform distribution give expected price and variance of price as

$$(11)\quad E(P_t) = (U_t + X_t)/2 = \tfrac{1}{2}\,[RG_t + [2(\gamma_C \delta C_{t-1} + \gamma_L \lambda V_{t-1})]/Q_t]$$

and

$$(12)\quad \sigma_{P_t}^2 = (U_t - X_t)^2/12 = RG_t^2/12.$$

Substituting equations (11) and (12) into equations (2) and (3) gives expected return and risk as

$$(13)\quad E(R_t) = \tfrac{1}{2}\,[RG_t + [2(\gamma_C \delta C_{t-1} + \gamma_L \lambda V_{t-1})]/Q_t]\, Q_t - C_t$$

and

$$(14)\quad \sigma_{R_t}^2 = Q_t^2 RG_t^2/12.$$

Finally, substituting equation (14) into equation (5) and then equations (13) and (5) into equation (4) gives land value as

$$(15)\quad V_t = \{\tfrac{1}{2}[RG_tQ_t + 2(\gamma_C \delta C_{t-1} + \gamma_L \lambda V_{t-1})] - \delta C_{t-1}\}/[a + b(Q_t^2 RG_t^2)/12].$$

By rearranging equation (15), the valuation formulation is given as a linear first-order difference equation

$$(16)\quad V_t - \frac{12\gamma_L \lambda}{12a + bQ_t^2 RG_t^2} V_{t-1} = \frac{6RG_tQ_t + 12\delta C_{t-1}(\gamma_C - 1)}{12a + bQ_t^2 RG_t^2}$$

or

$$(17)\quad V_t - \left(\frac{\gamma_L \lambda}{k}\right) V_{t-1} = [\tfrac{1}{2}RG_tQ_t + \delta C_{t-1}(\gamma_C - 1)]/k.$$

The solution value for equation (17) is given by

$$(18)\quad V_t = (V_0 - \varphi)(\phi)^t + \varphi,$$

where

$$(19)\quad \varphi = \frac{\tfrac{1}{2}RG_tQ_t + \delta C_{t-1}(\gamma_C - 1)}{k - \gamma_L \lambda},$$

$$(20)\quad \phi = \gamma_L \lambda / k,$$

and V_0 is some initial land value.

Policy Prescriptions and Land Values

The time path of land values is crucially related to the sizes of the policy parameters in the model. The general form of the time path is dependent on the size of ϕ in equation (18). Because $\phi = \gamma_L \lambda / k$, the path is determined by the relationship between the effective return on land allowed by policy ($\gamma_L \lambda$) and the market capitalization rate on land (k). If policy makers guarantee nothing above operating costs ($\gamma_L \lambda = 0$), the time path of land values is constant. If policy makers allow an effective rate of return less than the market rate ($0 < \gamma_L \lambda < k$), the time path is nonoscillatory and damped. If policy makers build in an effective rate of return equal to the market capitalization rate ($\gamma_L \lambda = k$), the time path is linear with positive slope. Finally, if policy makers set policy parameters such that the effective rate of return on land is greater than the market capitalization rate ($\gamma_L \lambda > k$), then the time path is nonoscillatory and explosive (figure 1).

Both the value maximum and the rate at which land values approach that maximum are influenced by support-price policy decisions. Although φ is a function of both γ_C and γ_L, ϕ is

[4] The expected distribution of returns with support prices remains unchanged even in times of increased supply and depressed market prices. Thus, even though the supply of land services may not be perfectly inelastic, the support price guarantees that expectations do not change concerning the annual net return of farmland.

[5] This assumption is necessary to conform to the assumption that the capitalization rate is constant over all time periods.

a function only of γ_L. So, changes in the proportion of operating costs covered by the support price affect the maximum that land values achieve over time. Changes in the proportion of land charges that are covered by the support price affect the land value maximum and the rate at which land values approach that maximum.

More specifically, the impact of changes in policy parameters on the time path of land values can be evaluated using comparative dynamics (Gandolfo, pp. 359–60). By differentiating totally the solution function (equation (18)) with respect to γ_C, γ_L, λ, and δ, the influence of policy parameters and exogenous factors can be discerned:

$$(21)\quad \frac{dV_t}{d\gamma_C} = \frac{\delta C_{t-1}}{k - \gamma_L\lambda}\left[1 - \left(\frac{\gamma_L\lambda}{k}\right)^t\right] > 0,$$

$$(22)\quad \frac{dV_t}{d\gamma_L} = t\left(\frac{\lambda}{k}\right)^t\left\{V_0 - \frac{[\frac{1}{2}RG_tQ_t + \delta C_{t-1}(\gamma_C - 1)]\gamma_L^{t-1}}{k - \gamma_L\lambda}\right\} + \frac{[\frac{1}{2}RG_tQ_t + \delta C_{t-1}(\gamma_C - 1)]\lambda}{(k - \gamma_L\lambda)^2}\left[1 - \left(\frac{\gamma_L\lambda}{k}\right)^t\right] > 0,$$

$$(23)\quad \frac{dV_t}{d\lambda} = t\left(\frac{\gamma_L}{k}\right)^t\left\{V_0 - \frac{[\frac{1}{2}RG_tQ_t + \delta C_{t-1}(\gamma_C - 1)]\lambda^{t-1}}{k - \gamma_L\lambda}\right\} + \frac{[\frac{1}{2}RG_tQ_t + \delta C_{t-1}(\gamma_C - 1)]\gamma_L}{(k - \gamma_L\lambda)^2}\left[1 - \left(\frac{\gamma_L\lambda}{k}\right)^t\right] > 0,$$

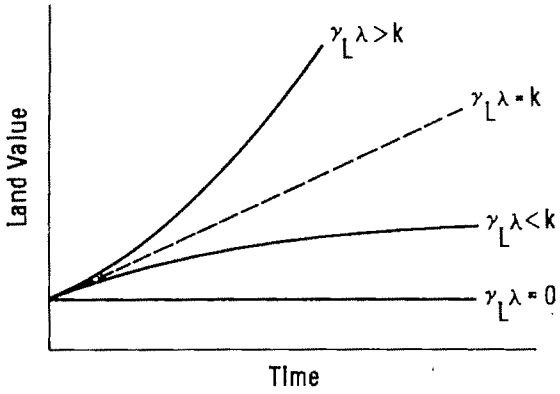

Figure 1. Time path of land values

and

$$(24)\quad \frac{dV_t}{d\delta} = \frac{C_{t-1}(\gamma_C - 1)}{k - \gamma_L\lambda}\left[1 - \left(\frac{\gamma_L\lambda}{k}\right)^t\right] \gtreqless 0 \text{ as } \gamma_C \gtreqless 1.$$

An increase in the proportion of operating costs covered by the target price (γ_C) *ceteris paribus* results in higher land values at every point in time. Increases in either the allowed rate of return on land (λ) or the proportion of land charges covered by the support price (γ_L) *ceteris paribus* also lead to higher land values at every point in time. An increase in the rate of inflation of operating costs (δ) *ceteris paribus* everywhere increases land values if more than 100% of operating costs are covered by the target price ($\gamma_C > 1$). If exactly 100% of operating costs are covered ($\gamma_C = 1$), an increase in δ *ceteris paribus* results in no change in land values. If operating costs are not fully covered ($\gamma_C < 1$), an increase in δ *ceteris paribus* leads to lower land values at every point along the time path.
